Just because a brush gives satisfactory commutation on a machine does not mean that it is the best brush for that machine. It may be wearing away the commutator too fast, or be developing too much friction, or too much resistance in the circuit, or too little control resistance resulting in high short circuit currents, any of which things tend toward loss and inefficiency.

Summary

The care and maintenance of D. C. machinery thus resolves itself into cleanliness, the proper care of bearings and lubrication, care of commutators, and the proper selection and use of brushes. Needless to say defects should be remedied as soon as possible after they become apparent.

The best engineers do their cleaning regularly and thus generally discover minor defects before trouble occurs which brings the defects forcibly to their notice and saves a large repair bill to the owner.

Alternating currents are described as those which, rising and falling in strength, flow alternately in opposite directions at regular intervals. The currents vary in intensity from a plus maximum to a negative maximum and are separated by points of zero pressure as distinguished from a direct or continuous current.

A commutator is that part of an armature which reverses the direction of electric currents in any circuit. It consists of copper bars or segments, side by side, forming a cylinder and insulated from each other, ordinarily by sheets of mica. It rotates with the armature and the conductors of the latter are so connected with the segments of the commutator that the current taken off by the brushes bearing upon its surface are direct although an alternating current is generated by the armature itself.

The Operators' Point of View

A DIGNIFIED PROTEST

The Editor, Power House,

Dear Mr. Editor:—

With reference to Mr. J. A. Carruthers' letter in the issue of Power House, July 20th, I crave permission to make a few remarks.

Mr. J. A. Carruthers, I think, has taken a ridiculous interpretation of the requirements of the Ontario First-class Engineer. A 200 horse power motor driven air compressor being a thing only seldom, if ever, met with, and then only in large plants in conjunction with steam apparatus. I do not intend being drawn into a controversy regarding the relative values of engineers' examinations in the different provinces, such being in my opinion merely small talk, but there may be readers of the Power House who may attach some weight to Mr. Carruthers' letter, and to them I make these remarks.

Before me, I have a copy of the "Alberta Steam Boiler Act," which plainly states that an applicant for First-class Certificate must furnish proof that he has been employed as a machinist, or boilermaker, at repairing steam engines or boilers for not less than 24 months, and that he has had charge and operated a battery of boilers and engines of not less than 300 horse power for a period of at least 12 months.

So why the disparity regarding the Ontario man?

W. J. Scott,
91 Pacific Ave., Toronto.

HOW ABOUT THIS

There is one thing with which many engineers are afflicted, a thing which tends to hold them back, to leave a wrong impression upon the mind of a stranger. The thing I refer to is a man's inability to talk freely to strangers or in public, in the lodge room or in his trade meetings. They may be good men in their particular line, it makes no difference. Among their everyday workmates they can, to use a slang expression "talk a fellow's leg off," but when in strange surroundings they become tongue-tied or vague in their conversation. I know, I am such a sufferer myself. Many a time after an interview I have cussed myself for a "bonehead" because I had become rattled. It has been stated that a complete knowledge of the subject under discussion and a confidence that you know the subject will prove a cure. I doubt it. Note the loud-spoken, know-it-all, but-really-know-nothing-fellow. He will talk you deaf, dumb and blind, and still say nothing. The poor chap who really could say something if he could remain normal finds it impossible to remain in this desirable condition, his voice gets husky, he perspires freely, and he talks about anything which enters his mind although he knows it will not be of any interest to his listeners. Personally I believe it is extreme shyness caused by a nervous temperament. What I am trying to suggest is not to misjudge a fellow when he tries to get off a speech and suddenly becomes tongue tied. It is the same when he tries to demonstrate on a blackboard, he knows exactly what he is going to write until he gets the chalk into his hand, then his mind becomes a blank. In familiar surroundings he can scribble stuff by the yard. Perhaps the lad who attends the meetings and never has a word to say or a thing to do is in this class. He may be eager to help but lacks the nerve, gall, moral courage, call it what you please, he may have all kinds of confidence in his own knowledge, it makes no difference. What is the cure I wonder. It is useless to advise him to talk slow, to take his time, etc., the ailment needs different treatment. Perhaps some of your readers would be glad to hear about a real cure. I know I would.

Owen Glendower.

Editor's Note

The trouble experienced by our correspondent is unfortunately only too frequently found among men of real ability. There have been some thousands of cures recommended, advertised, and sold by those eager to exploit the failings of their fellow men, but the cure for this trouble must come from within. It is a matter entirely of the mind, and is born of self-consciousness, begotten sometimes by nervousness, and sometimes purely shyness. It is a very serious handicap, and we have known some real good engineers who could not pass a verbal examination because they became a mass of nerves under the ordeal.

The only way to cure it is to think of the subject and not of yourself. Get away from the idea that everyone is watching for you to fall down, and realize that if you have anything to contribute that is worth while, your hearers are only too willing to hear you. Speaking in public may be a trying ordeal, but face the ordeal. After all, nothing very serious can happen to you. You could say all these things in a little circle of four or five intimate friends. Why not say them to 20, 40, or 100 if you have to.

This is one of the things where the meeting of a number of engineers in the room of their association can be of the greatest usefulness. This is the place where the man who is backward in placing his views on record should be encouraged, and the chairman or president of the gathering should encourage that type of man to speak, rather than those who are only too willing to speak on every occasion that arises, or even make occasions if none really exist.

FOOT VALVES ON PUMP SUCTION

Question:—The suction lift of a pump is approximately twenty-five to thirty feet. I have been told that I could get water with a suction lift of 50 to 60 feet by putting in valves 20 feet apart. If I have a lift of 40 or 50 feet and can get water with the valves does it matter if the valves are equally spaced?

Answer:—Whoever told you that putting foot valves on will enable you to lift water from a depth of 50 or 60 feet is mis-informed, and has not a clear understanding of what is entailed in the operation of pumping water from a depth. The absolute limit of lift with a pump which has an efficiency of 100 per cent, by which we mean that there is no slip and absolutely no losses due to friction of the water in the pipe, is 33.8 feet, which is the height of a column of water which could be supported by the pressure of the atmosphere 14.7 lbs. As no pump is 100 per cent. efficient, the maximum lift is something less than this and in practice rarely exceeds 26 feet.

There is, strictly speaking, no such thing as suction of a pump. What happens is that the pump plunger or piston exhausts the air from the suction pipe, and the pressure of the atmosphere forces the water up the pipe and into the pump. Obviously the greatest lift possible cannot be more than the height corresponding to the pressure of the atmosphere. This height is found from the formula $P = .434H$, or $H = 2.304\ P$, where P is pressure per sq. inch, and H is height in feet.

Electric Cranes

We manufacture high class Electric Cranes of every type and for every purpose.

Overhead Travelling Cranes for the most onerous work of lifting a complete locomotive or for the exact work of handling moulds and molten metal and for ordinary requirements where lightness and speed count most.

Giant, Goliath, Gantry and Transporter Cranes for shipyards, railway yards, and general manufacturing purposes.

ELECTRIC CAPSTANS

Electric Portal Jib Cranes fitted with Patent Balanced Lever-Luffing Jibs

Travelling and Stationary Jib Cranes with fixed radius jibs or fitted with Patent Balanced Lever-Luffing Jibs for use on docks, in shipbuilding yards and other places where the load must be handled at speed between obstructions that necessitate the radius to be altered frequently and as a part of the "cycle of operations."

SHEER LEGS to which Luffing-Jib may be applied.

CHARGING MACHINES for Open Hearth and Re-heating Furnaces.

WINCHES AND HOISTS

Conveyors

for handling raw materials such as coal, coke, ashes, clinker, ore, stone, lime, etc., automatically and with a minimum of labour.

The B. & W. line of Mechanical Handling Machinery includes Bucket and Tray Conveyors, Suction Ash Conveyors, Automatic Railways. and all the details thereof including coal and coke breakers, loaders, dumpers, weighing machines, etc.

We shall much appreciate an opportunity of going fully into details of any of our manufactures with intending purchasers.

Self-Promotion And Sales Promotion

Are you interested in any of these fields—power—metal working—marine? As a manufacturer, or purchasing agent, as a superintendent or foreman, as an ambitious mechanic or engineer?

Use These Publications

They will keep you strictly up-to-date in all branches of mechanical engineering. Edited by practical men. Cheerful, inviting, instructive, authoritative.

POWER HOUSE

Twice a month—$2.00 per year.
Serves the power plant engineer—Steam, Electric, Refrigeration, Hydraulic.

CANADIAN MACHINERY

Weekly—$4.00 per year.
Covers the metal working field—serving shop executives, purchasing agents and owners. First-class mechanical paper and market paper combined.

CANADIAN FOUNDRYMAN

Monthly—$2.00 per year.
A paper for the foundry owner, superintendent and foreman. Claimed by its readers to be unexcelled.

CANADIAN SHIPPING AND MARINE ENGINEERING NEWS

Monthly—$2.00 per year.
Interprets marine engineering in its broadest sense, serving the shipbuilders, navigation companies and their officers. (The Editor holds an extra first-class B.O.T. certificate).

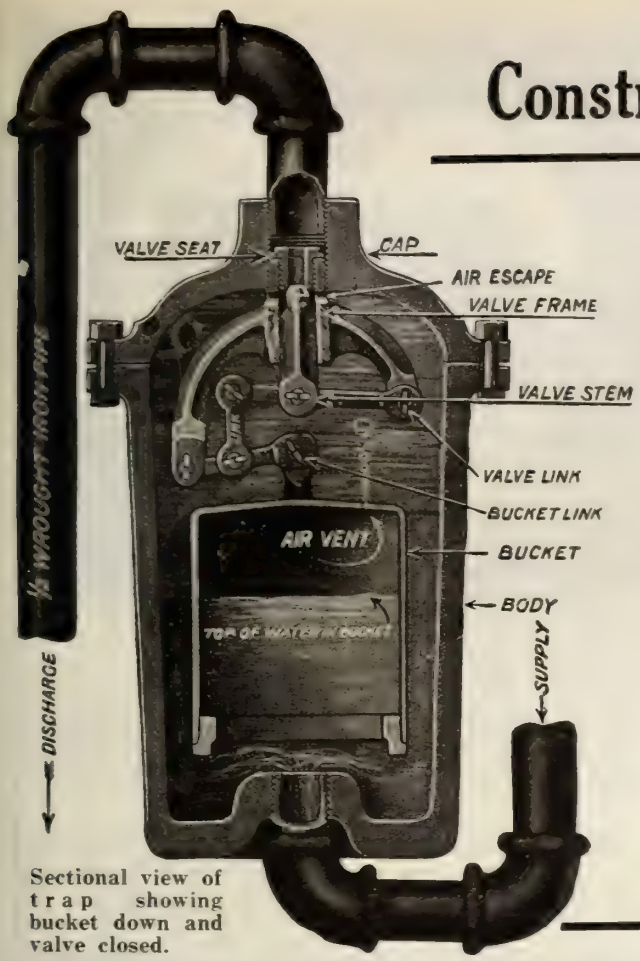
A Striking Message

A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. Here is the letter:

"I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. **This is a mistake on their part,** but for all I know to the contrary it may be due to the lack of energy on the part of the Power House ad. manager in getting after them. **It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages SO MUCH AS ON THE ADVERTISEMENT PAGES."**

Constructed to Save You Trouble



Sectional view of trap showing bucket down and valve closed.

The ARMSTRONG Steam Trap

was originally developed for use on the individual dryers or units of a paper machine, where the conditions are most severe and require a small trap of large capacity; a trap that will not become air bound, and will require practically no attention.

The Armstrong successfully met the requirements of paper makers, and since has been applied to practically all other fields with equal success.

The Armstrong Steam Trap has won considerable popularity because of its dependability, compactness and low cost. It has many exclusive features and embodies a principle which precludes the possibility of passing steam or of giving trouble. It is a trap mechanically simple, carefully constructed of the best materials and conscientiously backed by the manufacturer.

Columbia Recording Thermometers

Chart Changing Made Easy

Among the many exclusive features of S. & B. Recording Thermometers the ingenious Pen Arm stands out as an important innovation in recorder construction.

The Chart Changing operation on Recorders equipped with the ordinary rigid pen arm is a difficult one. The pen arm must be held away from the chart with one hand while the chart is changed. This is not only awkward but often causes a spilling of ink (perhaps spoiling the chart) and also strains the pen arm.

The special construction of the S. & B. Pen Arm and Ink Container makes chart changing the simplest operation. The writing arm is merely lifted from its supporting adjusting disc and allowed to drop to one side. This leaves both hands free to handle the chart. The exclusive S. & B. Ink Container is so constructed that there is no danger of ink spilling.

The many inquiries we are receiving leads us to believe we can best meet the general desire for definite information by dealing with the S. & B. exclusive features one at a time. This is the first —others will appear in the following issues of this journal. Look for them, they will interest you.

Your Forced Draft Is Just As Dependable As Your Fans

Upon the fan depends the efficient and uninterrupted operation of the boiler plant where blowers furnish forced draft.

C S C High Speed Fans insure never-failing service and have demonstrated their worth in power plants throughout the country.

With their self-aligning, spherical seated bearings —machined with extreme accuracy and lined with special babbitt metal—C S C High Speed Fans are built to give long-continued, dependable service under the most severe conditions.

The most important factor in the design of a high speed fan for forced draft is the wheel construction. A distinguishing feature of the wheels of C S C High Speed Fans is the use of annular rings, limiting the width of the blades and giving a tremendous strength with a minimum of weight—a condition most desirable in a wheel revolving at high speed. This construction makes possible the use of driving rings adjacent to the outer ends of the blades, keeping the wheel permanently concentric. No tie rods or tie rod adjustments are used, thereby eliminating possible eccentricity and an unbalanced condition.

The center plate, annular rings and the driving rings are made from solid sheets of steel accurately turned to size. This combined with the fact that the hubs are finished all over, inside and out, insures a perfectly balanced wheel.

Ready To-day--MacLean's Mid-Summer

All Fiction Number

BY WAY of an innovation, the August 1st issue of MACLEAN'S MAGAZINE has been produced as a Mid-Summer All-Fiction Number. The cover is by C. H. Taffs, the noted English artist who made such a hit with the cover of our January 1st issue this year.

There will be the usual Review of Reviews section, the Woman's Department, the Scoutmasters' and the Financial Departments; but, for this one issue, there will be no other serious original articles.

The chief feature of this issue will be a 42,000 word novel,

"THE JADE GOD," by Alan Sullivan

Never before has a complete novel been published in one issue of a Canadian periodical. In fact, there are few magazines in United States which have ever done it. There will be ten full pages of this novel at the front, well illustrated, as well as a generous turnover at the back of the magazine. In book form this one novel would sell for $1.75.

$1.75 Novel — **August 1st** — For Only 20c

Other big fiction features in the August 1st issue include—

"CHEESE," by Henry Holt, is the story of a business man who has spent his life manufacturing cheese—and made a big success of it. He suddenly gives way to an impulse which his wife cannot curb and which leads him through many ventures, New York, Paris, Monte Carlo—in all of which he learns to "take a chance."

"THE PINK PAGODA" is from the pen of Isabel Ecclestone McKay, that charming Canadian novelist who looks out on the world from her comfortable Vancouver home and who has achieved such a recent success with her book, "The Window Gazer."

"THE GUEST OF TRADITION" is a newspaper yarn by J. L. Rutledge. George Wilcox was a tradition around the old "Examiner" office and whenever cub reporters came on the staff they were urged to write like Wilcox. But Wilcox met a dainty little bit of femininity from the stage and the criss-crossing of their lives, and the wrecking of his ambition, are woven into an extraordinarily gripping tale.

"PER AGREEMENT" is by Archie McKishnie and is a mystery story told in this Canadian writer's best vein.

"HOOKS AND EYES," by Lloyd Roberts. Something is bound to happen when a bunch of New York chorus girls decide to venture into the Canadian wilds during the off-season (speaking theatrically), in order to get into condition for the rigors of their winter performances.

"THE TRYST OF THE WHITE LADY," by L. M. Montgomery. This is a delightful little love story with a very unusual turn to it, a story which measures up to the high standard which you expect from the author of "Anne of Green Gables."

"OVINGTON'S BANK," by Stanley J. Weyman. This is the next to the concluding instalment of this most popular serial.

Fig. 106
JENKINS BRASS GLOBE VALVE
(Standard Pattern)

Suitable for 150 pounds working steam pressure or 250 pounds working water pressure.

These Are Genuine Jenkins Valves

Note the name "Jenkins" inside the diamond mark on the body and the Jenkins signature beneath.

That's the sign that assures you lasting free-from-trouble valve service. It's the stamp of the genuine Jenkins—a mark it will pay you to look for when buying valves.

The line of Genuine Jenkins is very complete—valves in brass, iron and cast steel to meet every service requirement.

Fully pictured and described in Catalog No. 8—Free on request.

JENKINS
RAPID ACTION VALVE

Can be opened instantly.
Stays open automatically.
Stops water waste.
Saves time. Fitted with Jenkins renewable composition disc.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

Brine pumps, tanks, coolers and pipe connections covered with canvas-jacketed Nonpareil Cork Covering. Power plant in the General Motors Building, Detroit, Mich.

For Pipes and Fittings

IT IS not just the lines that have to be insulated. All low temperature equipment needs the protection afforded by Nonpareil Cork Covering and Lags. And all such equipment can be insulated with Nonpareil Covering. Look at the variety of apparatus in this picture and note how completely every piece of it that does not have to be left accessible is encased in an unbroken protective covering.

Nonpareil Cork Covering is made in accurately molded sections for pipes of ordinary sizes and for all screwed and flanged fittings in general use. For the larger pipes and fittings and for brine coolers and tanks, pumps, traps, separators and other irregular surfaces, beveled lags and discs are so readily adaptable that there is no excuse for leaving any low temperature surface in contact with the warmer air. In a single year, Nonpareil Cork Covering will more than pay for itself with the refrigeration it saves.

Nonpareil Cork Covering is made of pure cork granules, compressed in molds and baked to a uniform quality. Its natural gum, its mineral rubber finish, inside and out, and Nonpareil Waterproof Cement in the joints protect it from any possibility of moisture absorption.

Estimates of the insulation needed to protect your equipment will be supplied without obligation. Write for a sample and complete information.

Armstrong Cork & Insulation Co., Ltd.

MACLEAN STOKERS

MACLEAN STOKERS

Automatically control the coal feed and air supply to the furnace resulting in complete combustion of every pound of fuel used. Boiler tubes and heating surfaces are clean for longer periods because of the COMPLETE COMBUSTION.

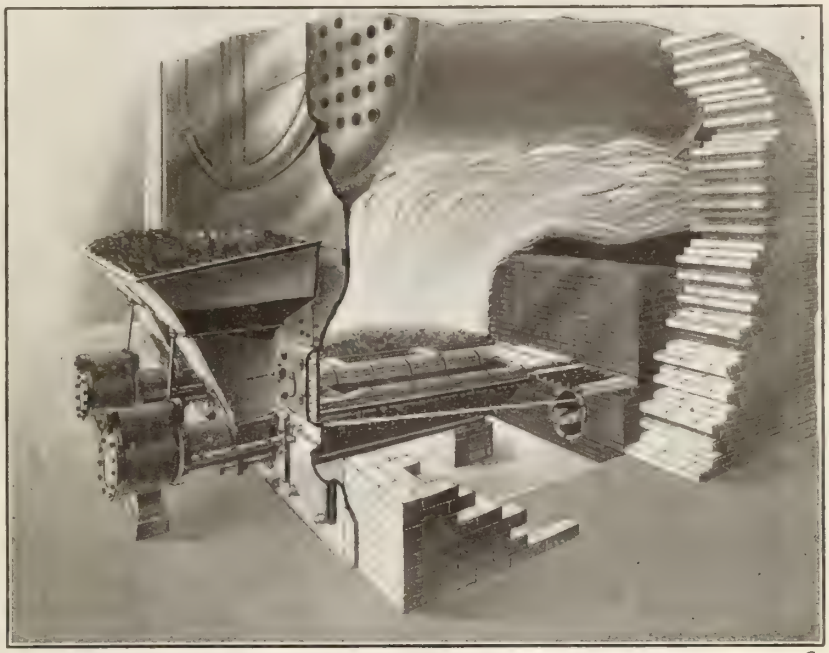
The MACLEAN STOKER **will not violate the smoke regulations of** any city, anywhere!

There are **no grates,** consequently **no siftings!**

Simplicity is the key-note of its construction and the fireman requires no special knowledge of stokers to operate it.

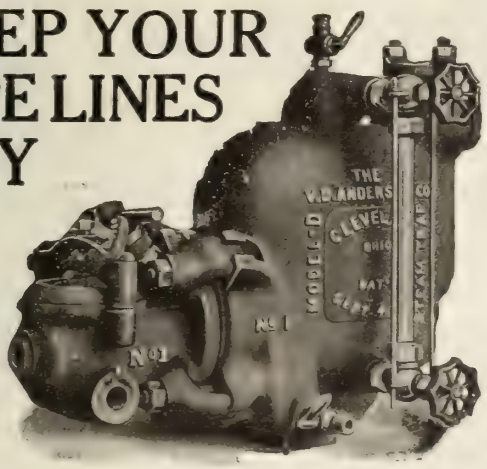
Maclean Underfeed Stoker Co.,
Limited

95-97 King Street, East,
Toronto Canada



The Coal it Saves
Soon Pays its Cost

KEEP YOUR PIPE LINES DRY



STEAM costs money and in order to obtain the highest efficiency from every square foot of heating surface in your plant it is necessary to distribute dry, hot steam and keep it dry by removing the condensation as fast as it accumulates.

This is just how the **Anderson Model "D" Steam Trap** works for you—it works automatically and continuously. No matter what conditions arise the Anderson Steam Trap stays tight.

Let us send you an interesting catalogue.

THE V. D. ANDERSON CO.
West 96th St., Cleveland, Ohio

DO NOT PASS THIS BY—

An emergency situation in the coal and transportation industries such as we have at present, always brings forcibly to our minds the absolute need of economy and efficiency in the boiler room. Yet these needs are always there if a business is to be really successfully managed. That is why we now suggest that you write us to-day for our booklet on the National Hand Fired Stoker—which effects most important savings — is applicable to your present boilers, using any type of fuel, and affords perfect stoking under all conditions.

More or Less Boilers?

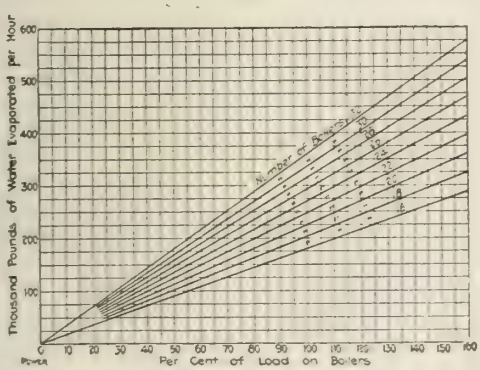

Chart showing number of Boilers to operate.

The VENTURI Meter

"VENTURI" Registered Trade Mark

Answers This Question

At this most critical time in American industry, when careful, far-sighted management is an absolute requirement for any successful business, why not squeeze every bit of energy from your costly fuel used in the boiler plant? The accompanying cut shows a chart devised by a prominent meat-packing concern, to make certain that enough and only enough boilers are used to take care of the load.

The vertical scale is in pounds of water being evaporated as shown by the Venturi Boiler Feed Meter; the horizontal scale is the load in percentage of boiler rating (it having been previously determined at what overload this type of boiler will generate steam with maximum efficiency); the diagonal lines represent the number of boilers in service. The diagram tells immediately whether more or less boilers should be in service for the rate of steaming shown by the Venturi Meter. This is only one of many ways to change the information given by the Venturi Meter into a real money saving which continues as long as the plant is operated.

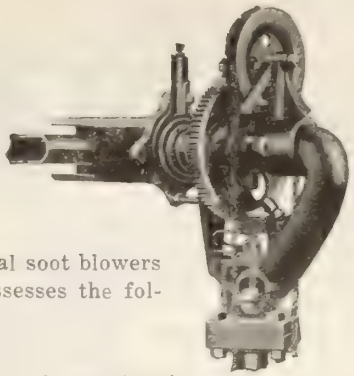
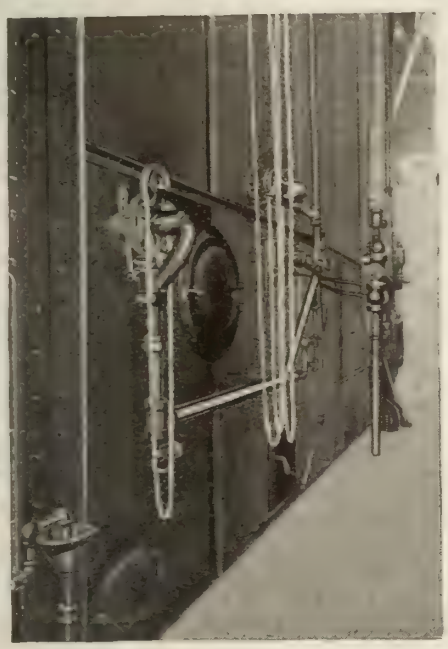
Five outstanding reasons Why you should install
Diamond Valv-in-Head Soot Blowers





As compared to previous mechanical soot blowers the Diamond VALV-IN-HEAD possesses the following distinct advantages:

1. LABOR FOR OPERATION—A saving of approximately 50 per cent.
2. STEAM FOR OPERATION—A saving of 50 to 60 per cent. or more.
3. PIPE, VALVES and FITTINGS—A saving of 50 to 66 per cent. in cost of pipe, valves and fittings.
4. MAINTENANCE—A reduction in annual charges of 25 to 50 per cent. or more. Practically complete elimination of condensate obtained.
5. EFFICIENCY—Greater cleanliness of boiler assured.

Remember that Diamond blower elements used in the hot passes of water tube boilers are CALORIZED. This special process—an invention of the General Electric Research Laboratories—prevents oxidation at high temperatures, and prolongs the life of the elements five to twenty times or more.

Write for Bulletin 287.

The Importance of the Technical Paper

The technical press has long ago proven itself a fine, progressive proposition, providing a service to industry that is not equalled in any other form of publicity.

To adopt technical paper advertising provides a desirable connection for any manufacturer.

The power plant owner, superintendent, or operator, always consults his technical paper—he reads it thoroughly—or as one subscriber recently wrote:

> *"It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages SO MUCH AS ON THE ADVERTISEMENT PAGES."*

The argument that the daily newspaper provides adequate "buying power" for the manufacturer of machinery, power plant equipment, etc., is unsound. The "Toronto Globe," in its issue of June 9th, 1922, said: "The newspaper on which hours were spent in less strenuous times, is now 'read' in ten or fifteen minutes at breakfast or after tea." Promote your advertising in the technical papers—papers that the users of your equipment depend upon.

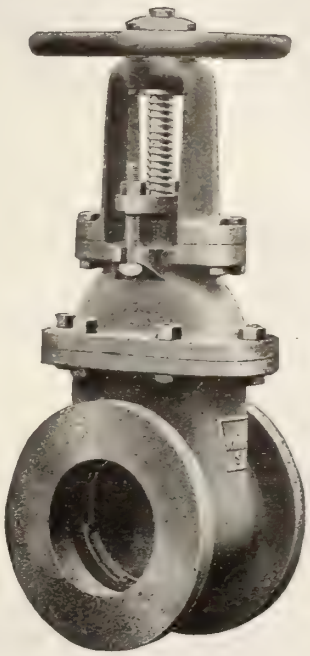
KERR



Valves of Quality

OUR long experience, together with the exercise of the greatest care with a view of designing the most modern and approved goods, is reflected in the satisfactory service given generally by KERR Valves.

In many cases KERR Valves have been adopted as standard equipment by engineers who appreciate the value of our guarantee—a guarantee based on the most rigid tests before the valves are shipped.

MADE IN CANADA

The Kerr Engine Co., Ltd.

Valve and Hydrant Manufacturers
Walkerville, Ont.

De Laval Oil Purifiers

are protecting the turbines and transformers of the Queenston Station of the Ontario Hydro Power Commission. After centrifugal purification or dehydration, no sludge or moisture remains in the oil to lower its insulating efficiency.

The De Lavals effect a saving of oil, prolong the life of the turbine and decrease the cost of transformer maintenance.

Wherever the preservation of oil efficiency is demanded—regardless of the size of the plant—there should be a De Laval.

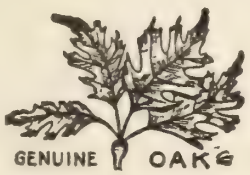
D K McLAREN

Genuine British Oak-Tanned
Leather Belting



What the Oak Leaf Means to You

It means that only the choicest part of selected hides has been used in the manufacture of the belting.

It means that the belting has been thoroughly inspected and tested and is properly representative of the D. K. McLaren high standard of quality.

It means that every foot of the belting has been subjected to the genuine British Oak Tanning Process, the long time process that, in some cases, is regarded as too expensive to be followed.

Together, these mean that you can depend upon every foot of D. K. McLaren's Belting to give you the utmost in service. The Oak Leaf is emblematic of the toughness, durability and gripping qualities—factors which play a big part in the reduction of your transmission costs to a minimum.

It's worth while looking for the Oak Leaf when you buy belting

TRADE MARK J.M.T. REGISTERED A GUARANTEE OF QUALITY

Products of Service

THE most valuable asset that any business concern can establish is Confidence and Good Will.

Steam Specialties, perhaps more so than any other commodity, stand or fall upon their reputation for absolute and unvarying quality.

The Confidence and Good Will built up by the Morrison line is a natural sequence of a conscientious effort to apply, to their manufacture, the skill and knowledge secured by over sixty years' experience.

So while this asset is a natural product of service, it stands equally as an essential for the continued security of users of the Morrison line.

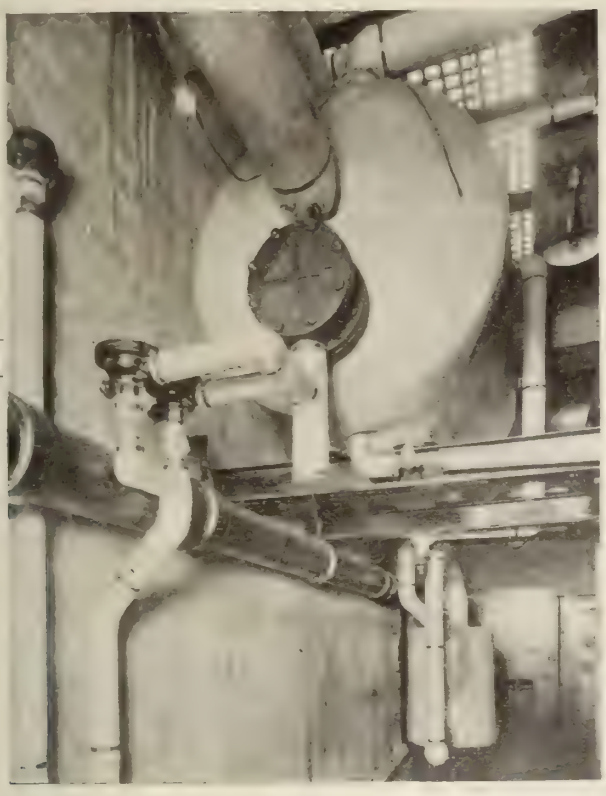
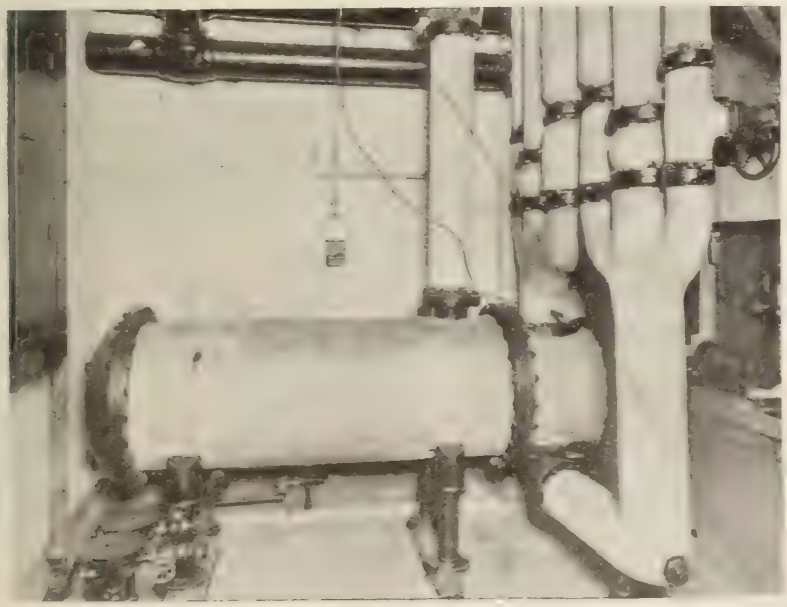
Sims Steam Tube Water Heaters



THERE are advanced features of design embodied in **Sims** heaters which distinguish them from other heaters—and **Sims** heaters are as superior in their service as they are different. **Sims** embodies straight tubes, 1½ in. O. D. Seamless Brass, rolled into a fixed head at one end, and a loose or floating head at the other. The tube structure is thus in no way attached to the heater. This construction admits of expansion and contraction of tubes without strain. Another feature is seen in the manner of grouping the tubes, which promotes the rapid circulation of water and allows for the best results in extracting the heat. **Sims** heaters have several other advantages. It is these advantages that have made **Sims** equipment preferred where large quantities of hot water, with live or exhaust steam as the heating water, are required.



The illustrations show Sims Water Heating Equipment at "Ardwold." Sir John Eaton's residence, Spadina Road, Toronto.

The upper illustration shows a 42 in. x 108 in. Sims No. 6 B.H. Clean E-Z Type Storage Heater for the Domestic Hot Water Supply. The lower illustration shows the Sims Converter, which supplies the swimming pool at "Ardwold."

WHY "MASON"?

Mason Standard Bronze Reducing Valve

THE splendid reputation of the Mason Engineering Equipment is not the result of an accident, but the expected outcome of forty years of persistent effort backed by large capital and superior manufacturing facilities.

They hold the first place to-day because their merits entitle them to that position.

No other devices work so accurately, wear so long, nor accomplish their purpose so fully as the Mason. Once installed they are always demanded thereafter, and thousands of manufacturers absolutely depend on these devices working in many critical locations and find them satisfactory. This is where Mason Service comes in. We have at your service a staff of engineers, specialists in the application of our devices. Their job is to see that you do not throw money away on unsatisfactory equipment, and to help you to choose equipment that will do the work required.

The Supreme Test—Service

THERE is only one test for a lubricant and that is "service"—service rendered under service conditions. The full benefit from capital sunk in expensive machinery can only be reaped through *correct* lubrication—*the best lubricants properly applied.*

Imperial Lubricants need no introduction. They are known and used from coast to coast. They are graded for every type of machine; are Canadian made from the finest crudes and readily obtainable in all parts of the Dominion.

Choose your lubricants from the Imperial line. Take advantage of our offer of free consultation. Both aim to assist you to insure that production shall bear a true relation to the time, thought and money expended in equipment.

Correct lubrication means the selection and proper application of the right lubricant for each machine. Correct lubrication actually promotes maximum profits, increasing production per unit and decreasing depreciation charges, fuel and repair bills.

Imperial Lubrication Engineers are at your service for consultation in solving troublesome lubrication problems. Their advice is free. Write to us at 56 Church St., Toronto, or to any of our branches.

WORTHINGTON S. D.
DOUBLE VOLUTE PUMP

"See our exhibit at the Sixth National Exposition of Chemical Industries, Grand Central Palace, New York, week of September 20th"

—another example of Worthington utility and efficiency

FOR general service in and around coal mines, there is no pump that enjoys a more favorable reputation or renders a more complete pumping service than Worthington S.D. Double Volute Pump.

For fire protection, for heads above single impeller limits, for unwatering mines—this pump can be standardized on, and because parts are interchangeable, repair bills and time losses are reduced to absolute minimum.

Simplicity of design is attained by using the double volute feature which eliminates diffusion rings, and because impellers are "back to back" there is no end thrust. This construction also results in minimum number of slippage points.

Worthington S. D. Double Volute Pump rounds out a full centrifugal pump service and typifies the wonderful 80 years old organization which sponsors it.

Other Worthington Products

Steam, Power, Centrifugal and Water Works Pumps. Meters, Oil Engines, Condensing Machinery, Air Compressors, Vacuum Pumps and Water Wheels.

To further enlarge their service, Worthington have acquired the goodwill and mechanical equipment of the Platt Iron Works, Dayton, Ohio, for manufacturing Oil Mill machinery, Hydraulic Turbines, Feedwater Heaters and High Pressure Air Compressors.

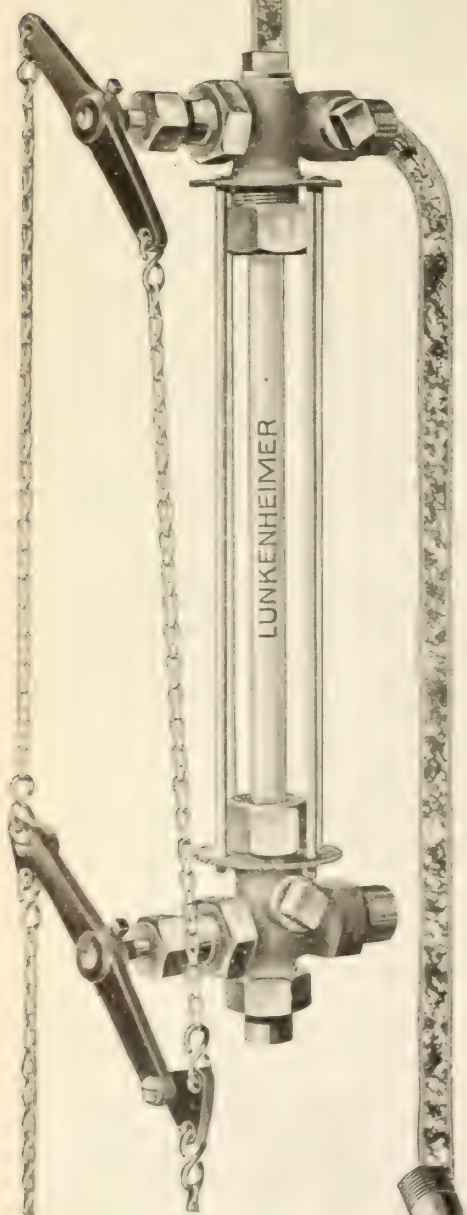
LUNKENHEIMER

WATER GAUGES, GAUGE COCKS AND FUSIBLE PLUGS



Absolute reliability in operation and maximum durability under the most severe operating conditions are the basic factors which govern the manufacture of LUNKENHEIMER WATER GAUGES, GAUGE COCKS, AND FUSIBLE PLUGS. These essential requirements, based on a thorough knowledge of operating conditions; the selection of proper metals for the specific requirements and Lunkenheimer "Quality" workmanship, have established the Lunkenheimer Line as standard for Safety and Economy.

Lunkenheimer WATER GAUGES are reliably accurate. The shut-off valves provide positive control in case of glass breakage and provision is made for the easy renewal of the glass should necessity require. Made in both Automatic and Non-automatic Patterns with Hand Wheel or Cross Lever Control.

Lunkenheimer GAUGE COCKS are substantial, positive in operation, and so constructed that a worn or broken part can easily be replaced. The variety of types made covers every service requirement.

Lunkenheimer FUSIBLE PLUGS are safety devices of merit. The fusible core is pure Banca tin and the Lunkenheimer method of filling the plugs precludes the possibility of chemical change during the process. This insures dependability in service Inside and Outside types in all sizes.

For Safety, Service, and Satisfaction specify LUNKENHEIMER and insist on their installation. Write for descriptive literature.

LINK-BELT TRAVELING WATER SCREENS

Every Power Plant Engineer Should Have This BOOK

LINK-BELT Traveling Water Intake Screens are a necessity in the modern power plant. They automatically remove all floating trash and debris, and insure a steady supply of clean water to the condensers. Uninterrupted operation is assured at all times regardless of the condition of water supply.

This book gives complete information. It shows what you can accomplish by atomatically screening water before it reaches the condensers. Use the coupon.

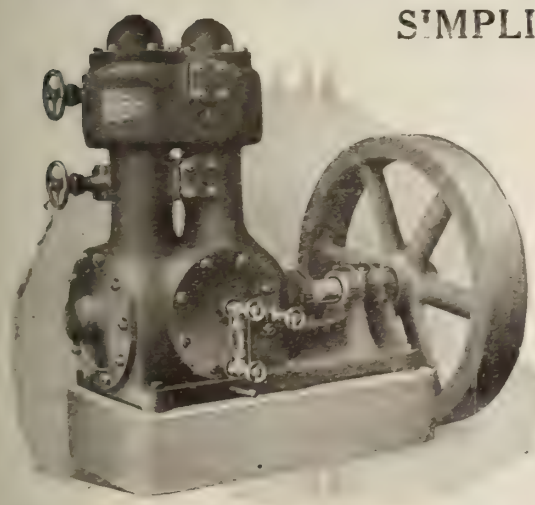
BURN ANY FUEL THAT HAS HEAT IN IT

York Enclosed Refrigerating Machines

SIMPLICITY—ECONOMY



After operating one of our Enclosed Machines for several years, one of our customers writes us that he has not spent one cent on it except for oil, and is still using the original charge of ammonia. This is a common experience among users of these Machines.

Simplicity of design and accuracy of construction permit them to be operated successfully by employees who, prior to the installation of these machines, never had any experience in operating one.

If you are finding the present scarcity of ice a burden to your business here is a simple and safe method of relief, and besides MECHANICAL REFRIGERATION pays good dividends on the investment.

Write us for information and prices.

Power Plant Firebricks

Conserve Heat and Cut Coal Bills

Increased boiler capacity and higher fuel economy are two of the advantages that follow the installation of Gates Power Plant Firebricks. They conserve furnace heat and permit a more even and more efficient condition of the fire to be maintained.

Gates Firebricks are easily installed in boiler linings and are so designed that when any part becomes fused a handy man can replace it in half the time it takes to repair a standard fire brick job. There is no possibility of costly air leaks and the many joints that clinkers stick to when ordinary firebrick is used are entirely eliminated. A complete stock of various sizes always on hand. Immediate shipments.

We specialize in all kinds of power plant brickwork. Boiler setting, Furnace building, Oven work and Repair Jobs. Get in touch with us!

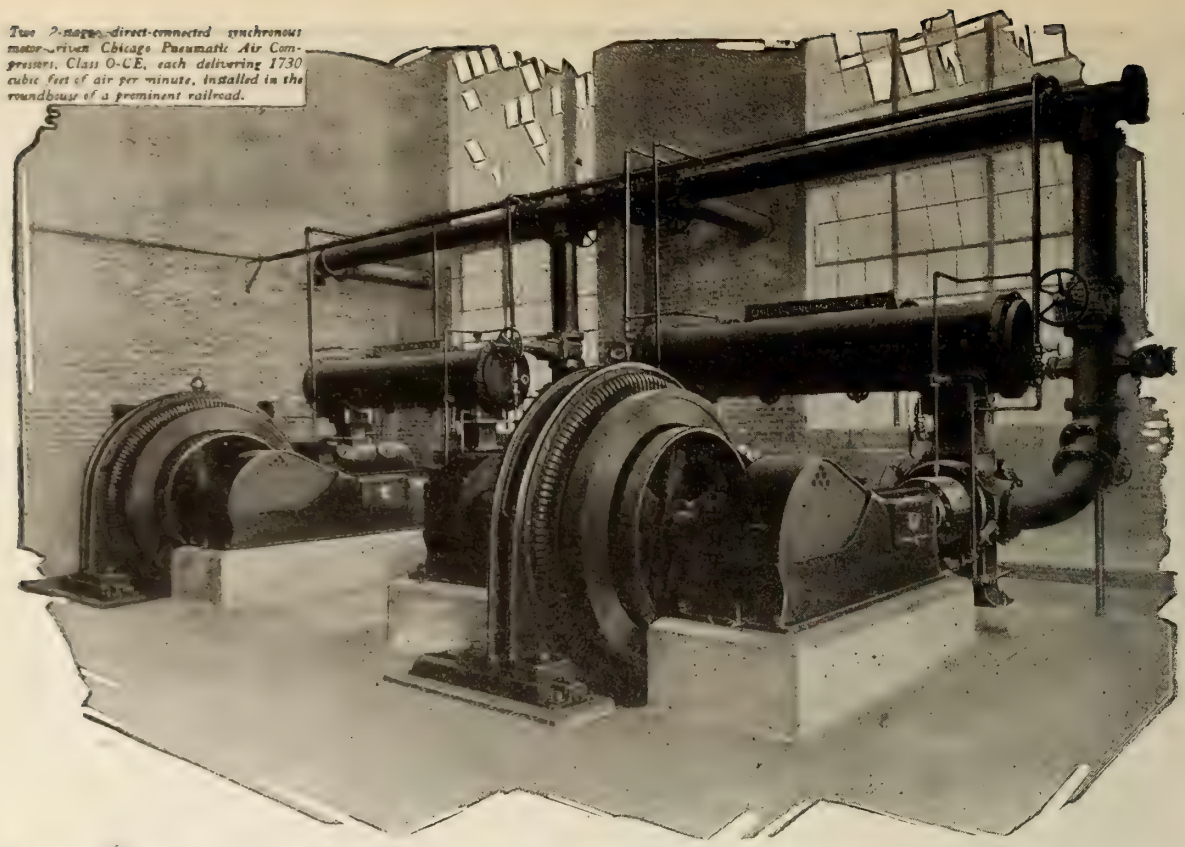
COPPUS TURBO BLOWER



Two 2-stage, direct-connected synchronous motor-driven Chicago Pneumatic Air Compressors, Class O-CE, each delivering 1730 cubic feet of air per minute, installed in the roundhouse of a prominent railroad.

An unloading system that saves power

DOES your air compressor pull against a vacuum *after unloading?*

Not if it's a Chicago Pneumatic whose unloading system permits the *free passage* of air through valves automatically held open when maximum receiver pressure is reached.

This one Chicago Pneumatic feature saves marked power over compressors in which unloading by choking the inlet pipe means power lost through working against a vacuum after unloading.

Strict power economy *before* and *after* unloading, and economy of floor space, make the direct connected motor-driven compressor illustrated an ideal power unit for—

Railroad shops, shipyards, structural steel plants, cement mills, packing houses, mines, oil refineries, glass manufacturing plants, textile mills, and miscellaneous manufacturing plants.

Know *all* the advantages of Chicago Pneumatics. Have you read Bulletin 400?

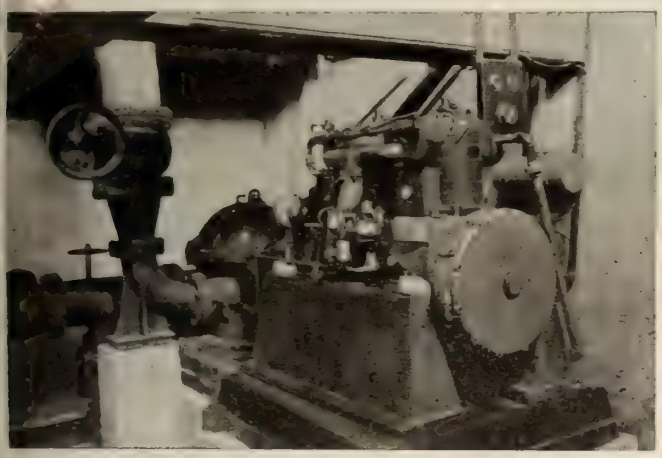
Sterling
THE ENGINE of REFINEMENT
For the finest boats that float

With a monthly fire loss of over $25,000,000 in the U.S.A., the cost of adequate fire protection fades to insignificance.

Many manufacturing plants and municipalities are meeting the need for fire protection economically with a Sterling powered centrifugal pump.

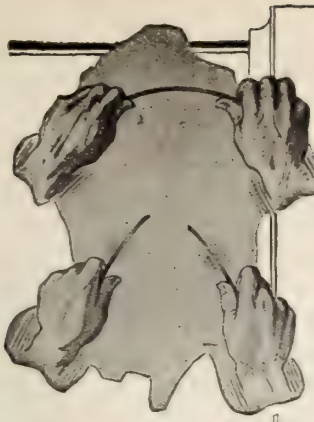


Nominal cost. High Efficiency.

Catalogue on request.

STERLING ENGINE CO., Dept. C-4, Buffalo, N.Y.

12 to 300 H.P. at Speeds up to 1,600 R.P.M.



broken blades are not always poor blades.

Often it's a case of a good saw used in the wrong way. A hack saw may be brittle as glass or flexible as a watch spring, according to the temper of steel, but the temper is only one of the things that go to make good blades.

Starrett Hack Saws are tempered, milled and selected according to the work they are designed to do. That's why they "cut quicker and last longer."

According to the Starrett system of blade selection, there's a saw for every metal. Many saws will cut more than one metal, but no single blade will cut all metals, or even all shapes of the same metal economically.

Starrett Hack Saws plus the Starrett Hack Saw Chart make it easier to cut metal economically. Ask for a copy of Chart CD—and "Hack Saws and Their Use"—both are free.

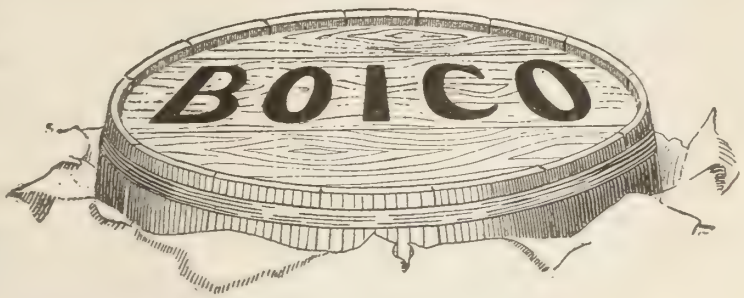
The Safe and Certain Boiler Cleanser

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.** BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.



Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

Plastic Fire Brick in modern high stoker-fired furnace, including side and front walls, door arches, bridge wall and baffles

Seamless One-Piece Boiler Furnace Linings

Betson's Plastic Fire Brick is not a brick nor a cement, but a plastic compound of fire clays of highest refractory properties. It is properly proportioned to eliminate expansion and contraction and is used to build completely, one-piece furnace linings and to replace laid up fire brick, tile or moulded-brick linings.

BETSON'S REG. U.S. PAT. OFF. TRADE MARK PLASTIC FIRE BRICK

is not high in price, it is high in efficiency. It is economical because it out-wears other linings and is so easy to install.

This plastic material is simply pounded into place with a mallet and smoothed with a trowel. No special forms, tools or training are required to execute a first-rate job.

With it tight, permanent baffles of proper size, shape and angle to form tapering passes, can be made for any type boiler, in your own boiler room, without disturbing your boiler setting.

Betson's is the pioneer and only Plastic Fire Brick. Backed by over 20 years' satisfactory service. Write for informing pamphlet.

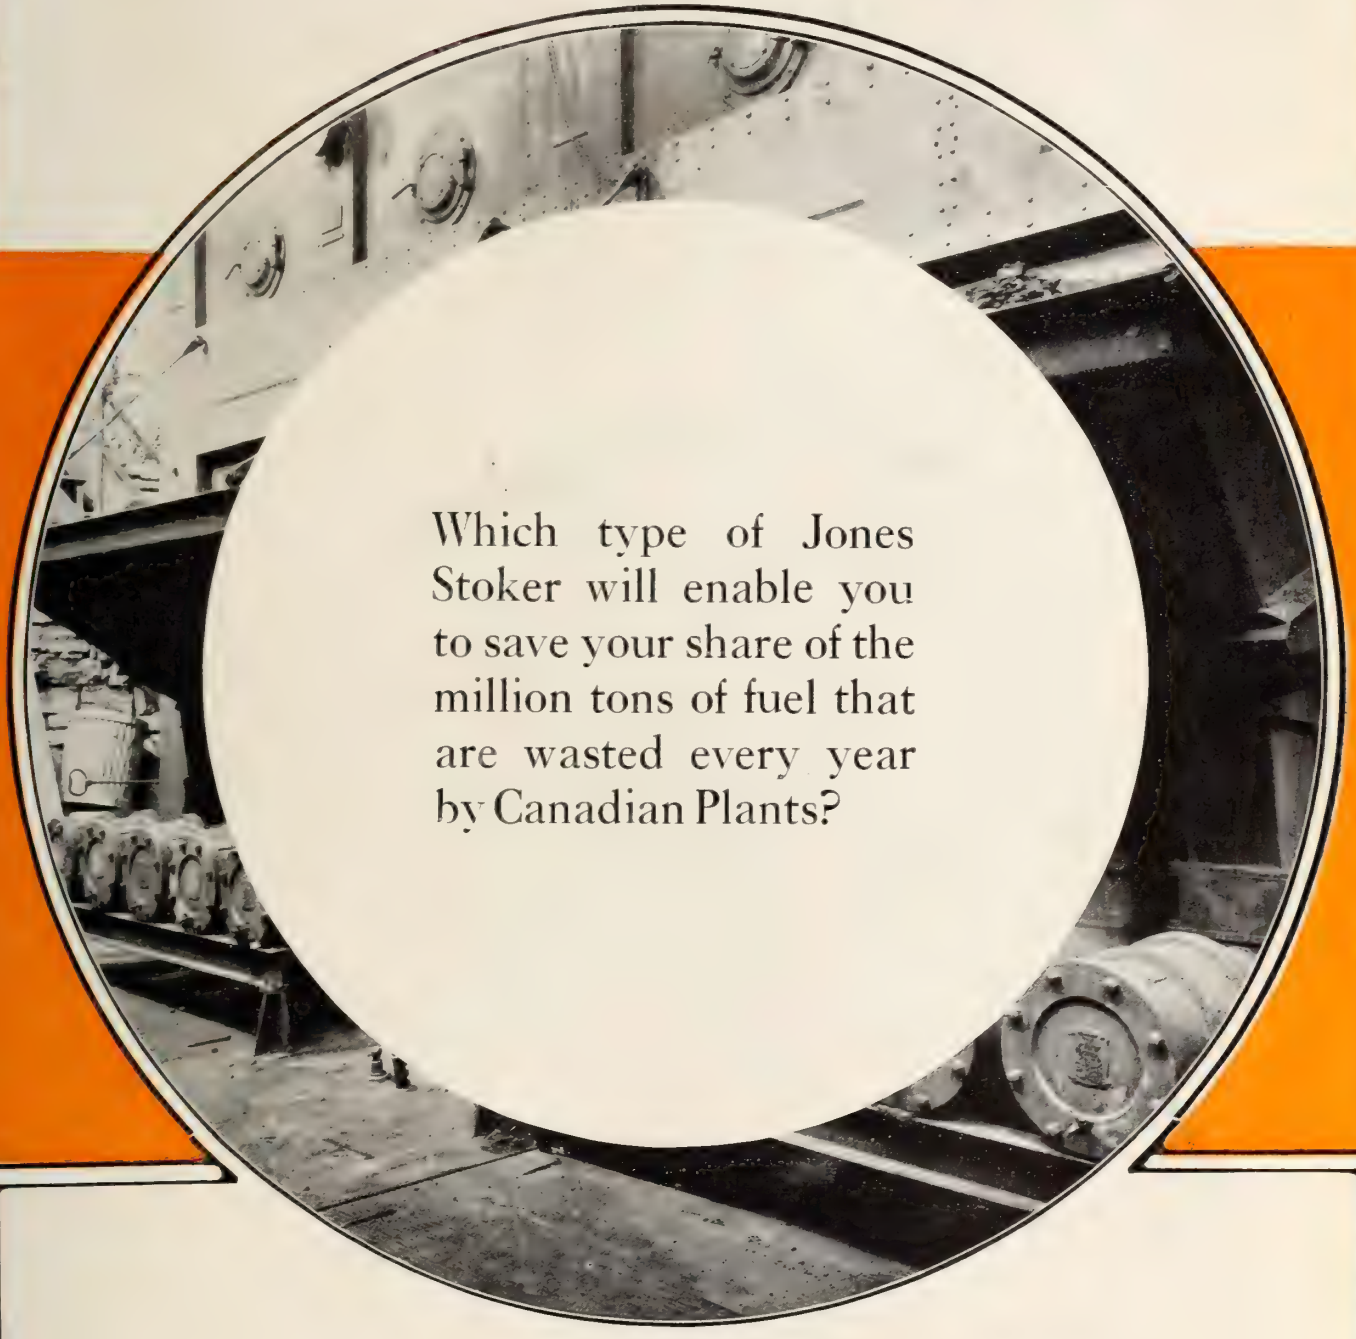
JONES

"A-C" and "Standard"

STOKERS



Which type of Jones Stoker will enable you to save your share of the million tons of fuel that are wasted every year by Canadian Plants?

Jones "A-C" and "Standard" Stokers are described in the following pages—

The JONES

Jones Stokers

for Plants of Every Type and Size

Jones "A-C"

Automatic-Cleaning, — Automatically-Controlled

JONES "A-C" Stokers are high-duty stokers. In many large plants from coast to coast they are operating continuously at heavy overloads. The automatic-cleaning ("A-C") feature saves labor. No hand cleaning is necessary. Clinkers are not formed on furnace walls. Fuel and air are automatically supplied in the right proportion for complete combustion with highest economy. Fires are automatically kept in perfect condition. Coal consumption is materially reduced.

Write for a complete "A-C" catalog

Jones "Standard"

Jones "Standard" Stokers are suitable for smaller plants. They can be installed under any boilers without disturbing boiler setting. No excavations are necessary. Like the "A-C" type, they are extremely simple in design and operation. Few moving parts—none in the fire. Foreign matter in fuel cannot cause damage. No shearing pins used. Very low maintenance cost. Smoke is prevented. Automatic fuel and air regulation insures best possible economy without expert supervision.

Write for a copy of the "Standard" catalog

UNDER-FEED STOKER

Made in Canada

The Service Behind the Stoker

THE Jones Under-Feed Stoker Company, Limited, has been reorganized, and its name changed to the Under-Feed Stoker Company of Canada, Limited. The following are the officers and directors of the Company:

President: Lloyd Harris, late Chairman of the Canadian Trade Mission, London, England; President Russell Motor Car Ltd.; President the Under-Feed Stoker Company of America.

Vice-President and General Manager: S. A. Armstrong, Vice-President and Managing Director of the Under-Feed Stoker Company of America.

Directors: T. A. Russell, President Willys-Overland Ltd.; Vice-President Russell Motor Car Ltd., and Director of the Under-Feed Stoker Company of America.

A. E. Holmested, Barrister, etc., and Director of the Under-Feed Stoker Company of America.

H. J. Fuller, President Canadian Fairbanks-Morse Company, Ltd.

David Fasken, K.C., President Excelsior Life Insurance Company.

This Directorate and reorganization makes available for all industrial Canada the engineering experience and development of mechanical stokers of the Under-Feed Stoker Company of America and the Under-Feed Stoker Company of Canada, Ltd.

This Canadian Company has carried on business in Canada for the past twenty years. Its stoker equipment is manufactured in Canada—is sold for Canadian money at par.

This is the only stoker company doing business in Canada to-day that is qualified from the standpoint of equipment to handle any type of combustion problem presented.

The Under-Feed Stoker Co. of Canada, Ltd.

WAIT STEAM TURBINES

The Acme of Perfection

MANY recent improvements in detail by skilled investigators have resulted in the G. & McC. Co. "Wait" Steam Turbine reaching a high point in efficiency—it is in fact recognized by leading engineers as the acme of perfection in steam turbines. Some of its leading features include in addition to high efficiency—simplicity, ruggedness and economy of operation.

Points of this G. & McC. Co. Machine that should be remembered are:

—The Turbine is entirely automatic.
—No oil or grease cups.
—Stuffing boxes and glands, seldom require attention.
—Emergency governor and valve are entirely separate from main governor and valve.
—Interior may be easily inspected.
—Self-lubricating; dust-proof; dirt-proof.
—Speed can be changed while running.
—LOW RUNNING EXPENSE AND COST.

Experiments on a Conveyor-Feed Type Stoker

As a Result of Two Years' Experimental Work, a Stoker Which Will Burn Eastern Bituminous Coal Successfully Has Been Obtained—The Author Describes Them in a Paper Before the A.S.M.E.

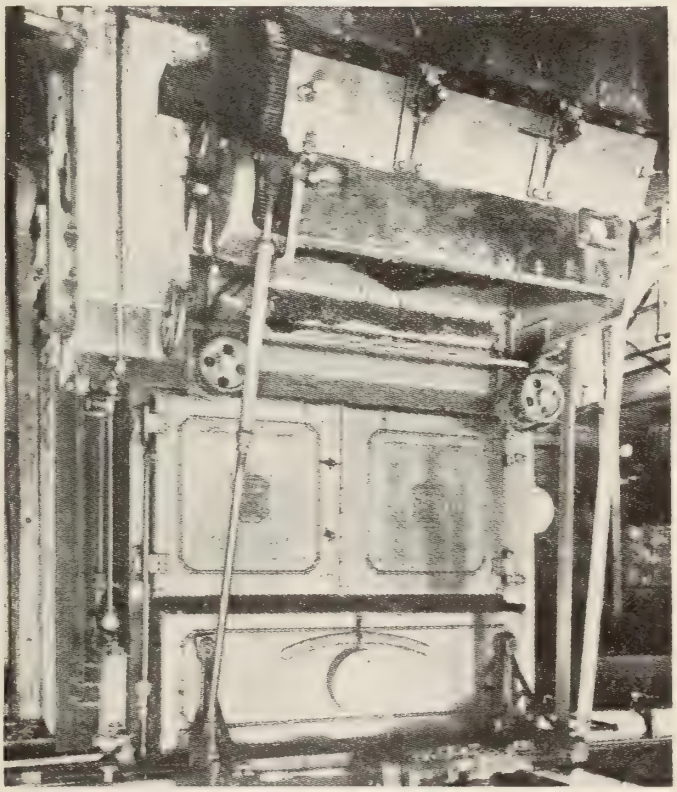
By LLOYD R. STOWE

FOR the past two years the Laclede-Christy Clay Products Company has been experimenting on a new forced-draft stoker for use with the various kinds of fuel found in this country. The boiler house of this company's Christy plant at 4600 South Kingshighway, St Louis, has been and still is being used for experimental, testing and development work. Fig. 1 shows the test boiler and stoker.

The burning of coal has always been a decidedly popular subject with engineers and naturally these two years of intensive experimentation have developed information that will be of interest to the members of this society. The stoker used employs the conveyor method of feeding, i.e., it uses progressively moving chain-grate conveying elements to feed the coal through the furnace and to discharge the refuse to the ashpit.

At the outset it is necessary that we realize the full import of the term "conveyor-feed." The conveyor-feed principle makes possible the use of grates that continually move onward in one direction. The fuel bed being supported on these moving grates is positively conveyed from the stoker hopper where fresh coal is introduced, to the discharge end where the refuse is rejected to the ashpit.

The feature of the conveyor-feed that commends its use is its handling of the fuel bed in a positive, definite fashion. By striking off the fuel evenly under a feed gate and then literally carrying it on through the furnace and over the point of ash discharge, this mechanism prevents in a large measure the evils of less positive feeding devices, namely, specifically uneven fires, balled-up spots, and immovable clinker formations. These advantages of conveyor-feeding are very attractive to the stoker designer, and as a result of this and of the fact that the underfeeds have quite thoroughly demonstrated the great advantages of mechanical draft, many builders are now experimenting on and developing various forms of forced-draft conveyor-feed stokers. In fact, work in this direction characterizes the efforts of the stoker industry at the present time, and the following particulars regarding the experimental work of the Laclede-Christy Company and the results it has attained should therefore prove of timely interest.



THE TEST BOILER AND STOKER.

It is well known that there have been many failures in attempting to burn eastern coal on chain grates. In fact, some have gone so far as to maintain that the undisturbed fuel bed of the conveyor-feed is so poorly adapted to eastern coal that it is useless to proceed further along these lines. Others have, in all sincerity, advised manufacturers to stay with the western coals, where the conveyor-feed rightfully belongs.

Now, one of the characteristics of the conveyor-feed, it will be observed, is that the fuel bed is undisturbed during the so-called coking period, or, more properly speaking, the period of destructive distillation. It is largely because of this feature that the author has elected particularly to relate what has been learned about eastern coals with conveyor-feed—coals high in heat value and low in ash and including those termed semi-bituminous and caking. And it may be as well to state at this point what may be considered as the conclusion of this paper: Namely, that the results of these experiments undertaken indicate that conveyor feeding can be used successfully with eastern bituminous fuels.

For many years it has been quite clearly established that nearly every re-

quirement of a successful stoker is lacking when burning caking fuels on chain grates with natural draft. The coal cakes almost immediately upon entering the furnace, high rates of burning cannot be secured, the combustible content of the ash is high, the admission of the air is not properly graduated to the requirements of the various stages of combustion, and maintenance of links is excessive. This is indeed a complete indictment, and with the sole exception that the automatic features are always in evidence, it may be said that the performance of chain grates on eastern bituminous coals violates every requirement of a successful stoker.

It is well known that the caking property of eastern coal is the most serious obstacle in the way of the successful use of this fuel on chain grates. In endeavoring to burn Pocahontas and similar coals it is observed that tarry oils flow through the fuel bed as a result of the application of heat at moderate temperatures. It is further observed that the coal under the arch is caked or coalesced by these tarry oils, and forms a sticky blanket that prevents the entrance of air through the coal and hence checks combustion and heat generation under the arch.

In attempting to remedy this situation the most natural thing to do is to employ mechanical means to break up the caked fuel bed, which is the course almost invariably taken by the inventor. In fact, the idea is prevalent that "A mechanical agitation of the fuel bed, for the purpose of breaking up the coke, is necessary or advisable when burning eastern coals." So many statements have appeared similar to the one just quoted that mechanical engineers have come to accept it as a basic fact. The results obtained at the experimental plant, however, have disproved this contention and in doing so have made possible the application of conveyor feeding to the burning of eastern coals.

Causes of Coke Formation in Stoker Practice and Its Prevention

All bituminous coals have a small resinous content that flows when heat is applied. In certain coals this resinous material has decided adhesive or binding properties and hence agglomerates the coal particles into a primary mass when it flows under the application of heat. This mass is the starting point of coke formation and out of it true coke may be formed by further actions that take place in the fuel bed. It must be noted here that while all bituminous coals have this resinous content its adhesive or binding property is lacking in the western, or free-burning coals.

It appears that the higher the oxygen content of the coal, the less pronounced will be the primary caking tendency. Analyses on a moisture-and-ash-free basis show that eastern coals contain less than half as much oxygen as do western coals of non-caking characteristics. Furthermore it is well known that eastern coking coals lose their caking properties by weathering, and it has been determined that weathering causes coal to absorb oxygen and to increase in weight by the weight of oxygen absorbed.

The absorption of oxygen can be accelerated and be made to take place in the boiler furnace by producing very high coal temperatures and accompanying these with a plentiful supply of air. In other words, this feature of weathering can be artificially carried on in an exceedingly short time. The oxygen absorbed apparently destroys the adhesive qualities of the resinous material referred to above and hence the primary mass from which the coke structure is later formed is not produced.

Again, when heat is applied to any bituminous coal, a chemical rearrangement or breaking down of certain of the compounds in the coal takes place. This action produces the greater part of what is termed "volatile matter," the remainder coming from the resinous content. The initial product of this chemical rearrangement is no doubt further decomposed into a fixed gas and a tarry residue. This tarry residue has not in itself the properties of a very strong binder, but it does build up and materially strengthen any primary coke structure that may already be present by leaving a film of carbon behind when the final breaking down into this carbon and fixed gas has taken place.

The foregoing theory accounts for the non-caking performance of eastern coals in the experimental work referred to in the present paper, and in its essentials seems to be the theory most commonly accepted by coal and coke analysts.

In the experiments with the new stoker the ignition temperatures are extremely high and at these temperatures considerable amounts of air are forced through the fuel bed, thus providing for the absorption of sufficient oxygen in a short time to destroy the initial caking tendency. Moreover, it is reasonable to suppose that these unusually high temperatures at the same time cause a quite different procedure during destructive distillation than that which obtains with lower temperatures. That is, these extremely high and unusual temperatures completely decompose both the resinous excretion and the remaining or major part of the volatile-forming matter before the former can set up an appreciable primary structure, and before the carbon of the latter can have time to impregnate any slight primary structure that may have formed.

The absence of coke formation changes completely the character of the fire under the arch and has almost as marked an influence on the last half of the fire because since coke is not formed in the distillation zone the cemented coke lumps cannot be present in the final stages of combustion. The individual pieces of coal retain their identity exactly the same as when Illinois coal is used, with the result that the fuel bed has the soft, incandescent and fluffy appearance which every chain-grate fireman realizes means economy and high rates of burning. The absence of coke formation in the final stages of combustion will be mentioned again.

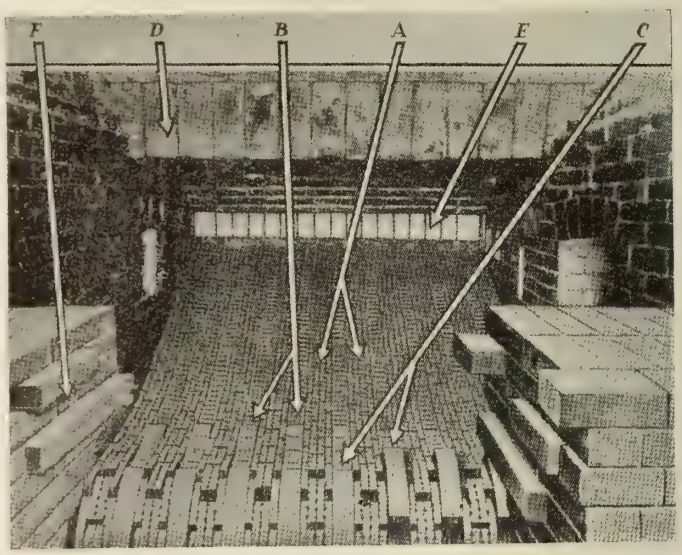


FIG. 2—VIEW OF THE GRATE SURFACE AND FURNACE TESTED.

The New Stoker

A description of the final apparatus decided on is advisable at this point for the purpose of showing how the high initial temperatures are obtained. Fig. 2 is a view of the grate surface, its general incline being 20 deg. The arrows indicated by A point to narrow chain grate or conveying elements, about 4 in. wide and placed on 7-in. centres. In the intervening 3-in. spaces are placed stationary tuyeres indicated by arrows at B. At the lower end of the grate surface the tuyeres B terminate in short pivoted bars C which are made automatically to rise above, then drop below, the surface of the conveyor chains. This action takes place slowly. D is a feed gate, adjustable to give various thicknesses of fire exactly as on a chain grate. Partly overhanging the vibrating bars C is the bridge wall E, shown cut away in the centre. An ignition arch

is shown at F. This latter provision conforms to chain-grate practice except that with the greater incline of the grate the arch is farther away from the fire. Fig. 3 shows a cross-sectioned side elevation of the stoker and boiler.

Close study of chain-grate practice has revealed much in the art of building up high ignition temperatures. A great expanse of bridge wall extending from a point horizontal with the arch to or nearly to the fuel bed is known to be of utmost value in directing heat on to the incoming fuel. This is the surface indicated by A in Fig. 3. The steep incline of the stoker in question permits this dimension A to be greatly extended over that possible with the ordinary chain grate. Moreover, it exposes the fuel bed more directly to the intense heat reflected from the bridge wall and the flame in front of it.

The form of arch was also taken from chain-grate practice and its design and placement has, of course, contributed its part toward the building up of the high fuel-bed and ignition temperatures that play so important a part in preventing the caking and ultimate coking of the fuel.

As to the admission of a generous supply of air (the second requirement for coke prevention), the greatest percentage of the total air supply is supplied under moderate pressure through that part of the fuel bed under the arch. This air supply, coupled with the very high fuel-bed temperatures obtaining, quite effectively destroys any inherent caking tendency of the fuels thus far tested, and made it possible to burn eastern coal with a considerable degree of satisfaction.

In view of the troubles known to exist with eastern fuels when using a stoker that conveys the fuel undisturbed into the furnace, the author deems it advisable to give a further description of the stoker in question in the light of what is required today in the economical burning of coal for the generation of steam, touching particularly on those features that have been conspicuously faulty in chain grates. The following outline presents the entire situation at a glance, and later in the paper each of the items therein is briefly touched upon.

It is of interest to note that the difficulties with chain grates on eastern coal have been violations of the essential requirements of the modern stoker, so it is not surprising that the opinion prevails that success cannot be obtained with eastern coals using the conveyor-feed.

An adequate treatment of the first-mentioned stoker requirement in the foregoing outline would entail a discussion of what takes place in the fuel bed and would involve a consideration of the various types and feeds of stokers, but as such a discussion is outside the purpose of this paper this requirement will be discussed only as to the essentials upon which everyone will readily agree.

Present-Day Requirements of an Automatic Stoker Compared With the Performance of Chain-grate and Conveyor-Feed Stokers, Each Using Eastern Coals.

	Requirements of the Present-Day Stoker.	Results Obtained with Eastern Coals. With Chain Grates	Results Obtained with Eastern Coals. With Conveyor-Feed Stoker Described
1	It should completely burn all combustible that arises from the grate, and perform this task under the great handicap of using no more air than is required	Thin fires spotted with upstanding coke result in excess air and low CO_2 due to the fact that the air supply is not graduated down to a minimum at the rear of the stoker and to influence attending the coking of the fuel bed	Graduation of air supply and thickening of fire near point of ash discharge and the prevention of coke assure a consistent 10 to 12 per cent. CO_2 content with positive assurance of an intimate mixture of air with combustible gas.
2	It should bring about low combustible in the ash.	Combustible in the ash from 30 to 50 per cent.	Combustible in the ash from 16 to 24 per cent.
3	It should burn coal at high rates of burning — not only to obtain high capacities but to widen the range of economical rates of burning as well, in order that great flexibility may be assured.	Rates of burning from 25 to 35 lb. of coal per sq. ft. of grate surface per hour.	Rates of burning up to 60 lb. of coal per sq. ft. of grate surface per hour.
4	It should be as nearly wholly automatic in operation as possible.	Successful in the matter of automatic operation.	Successful in the matter of automatic operation.
5	It should not entail unreasonable expense in the upkeep of the grate surface or of the furnace brickwork.	No unusual maintenance cost for furnace brickwork, but a very high one for grate links.	Use of mechanical draft imposes a more severe condition for furnace brickwork, requiring a higher grade of refractories, but maintenance of ironwork is not excessive — in fact, may be considered quite satisfactory.

Air Distribution

Rather exhaustive surveys of the gas composition in various parts of the furnace were made frequently during the development work. These surveys showed that the zone of destructive distillation yields far greater quantities of combustible particles than does that well-spent portion of the fuel bed near the bridge wall. It follows, then, that air distribution must be regulated to supply large quantities of air to the coal during the early stages of combustion and limited quantities as the fuel nears the place of ash discharge.

It will be generally admitted that in order to burn completely all the fuel with a minimum of air it is of prime importance to provide each particle of combustible with its own quota of oxygen-giving air just as it rises from the fuel bed. The tuyere construction is well suited to such a requirement and lends itself admirably to these experiments. The tuyeres are cast in interchangeable sections containing varying percentages of air openings. This feature permits any desired gradation in air spaces to be made, between the two extremes noted in the tabulation below.

It is important at this point to recognize that the wind-box pressure is uniform under the entire grate. This provides high draft intensity and high air jet velocity for all parts of the fuel bed.

Low Combustible in the Refuse

The reduction of the combustible in the refuse to a satisfactory figure was brought about by taking advantage of the four following factors that have a vital influence on the character of the refuse: (1) Strong ignition; (2) A free-burning fuel bed; (3) Thickened fuel bed near the discharge end of the stoker; (4) High draft intensity through the nearly spent fuel.

The strong ignition temperatures have been referred to previously. On the conveyor-feed type of stoker, the coal burns from the top downward during the early stages, and from the bottom upward during the remainder of its travel. The higher the ignition temperatures, the quicker this reversal is established. An early burning from the bottom upward is recognized even in chain-grate practice, as being most effective in bringing about low combustible content of the refuse.

In a caked fuel bed of eastern coal, the air breaks through only at the fissures or cracks. Naturally the burning starts only at these fissures, and as it continues, holes are formed in the fuel bed. As the holes increase in size, the rate of burning decreases, due not only to the cooling ef-

Table 1—Air-space Distribution Adopted for Conveyor-feed Stoker.

22 per cent. of 40 per cent.	= 8.8 per cent.	2 per cent. of 40 per cent.	= 0.8 per cent.
Total air space	=13.6 per cent.	Total air space	= 5.6 per cent.

Conveyor elements, about 60 per cent. of total grate surface.
Tuyere elements, about 40 per cent. of total grate surface.

fect of large columns of cold air but also to the lessening intensity of draft occasioned by the increase in the effective air openings. This action results in a fuel bed characterized, in the final stages, by isolated lumps of coke surrounded by patches of bare grate. To prevent exceedingly low CO_2 the operator must run these bare patches out of the furnace and consequently dump the intervening or accompanying coke lumps into the ashpit.

With coking prevented and with each individual particle of coal preserving its identity, the air filters upward evenly throughout every part of the fuel bed. Freed from localized burning the fire now appears soft, intense and highly luminous.

The thickened fuel bed near the discharge end is brought about by the retarding mechanism described. (See Fig. 2.) When elevated the short pivoted bars C raise the nearly spent fuel above the chains, thus holding it back, and when depressed permit the conveyor elements to carry the ash out of the furnace. The relative duration of these two influences can be controlled by the operator and the fuel bed near the discharge end of the furnace can be held back and thickened to any desired depth.

The high draft intensity in connection with this thicker fuel bed has already been mentioned under the paragraph on air supply. Full wind-box pressure at this part of the grate forces high velocity air jets into the thickened bed and hence is particularly advantageous in burning out the remaining particles of combustible.

High Rates of Burning

From the foregoing references to mechanical draft it is quite apparent that high rates of burning are attainable with this new type of stoker. The replacement of the typical plastic fuel bed with the free-burning, intensely active bed obtained with the new equipment, materially assists in securing higher rates of coal consumption. High CO_2 results quite naturally from (a) the proper air distribution described; (b) the thicker fuel bed particularly at the discharge end; (c) the higher fuel bed temperatures that cause increased chemical activity; and (d) the impinging jet action on the fuel particles produced by small air spaces and forced draft.

FIG. 4 DETAILS OF THE CONVEYING ELEMENTS MARKED "A" IN FIG. 2.

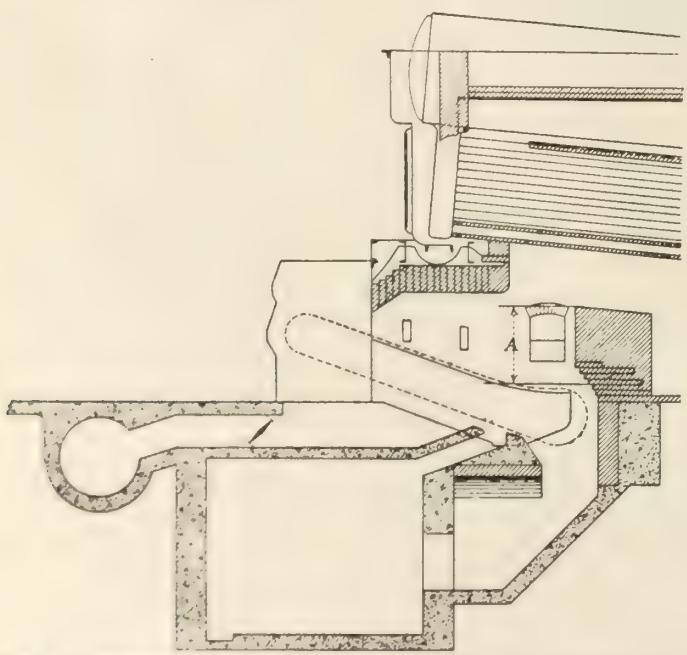

FIG. 5 SECTIONAL ELEVATION OF BOILER AND STOKER.
[illegible] heating surface and stoker 40 sq. ft., ratio 62½ to 1.)

Automatic Operation

In the matter of automatic operation it is only necessary to recall the basic principle of the conveyor-feed stoker — a positive feed fuel coal hopper to ashpit. The only action that interferes with this automatic and continuous performance and requires more than a minimum of attention from the operator is the formation of clinker on the side walls. This clinker accumulation is no more serious than with chain grates but experiments are under way to still further minimize the evil.

Eastern coals require less side-wall slicing than do those from the Middle West, probably because of the lower ash content with its higher fusing point. Also such coals have higher heat value and hence greater firing stability than Illinois coals. Because of these two advantages, the firemen of the experimental plant prefer eastern coals to those from the Central West when burned on the new stoker.

Low Maintenance

The thin uneven fuel bed at the discharge end of a chain grate combined with the low ash of eastern coals exposes the grates to the heat of the furnace. Moreover, with caking coals and chain grates, the procedure of partially closing the damper to raise the CO_2 content of the gases is too often resorted to, and such a practice invariably results in over-heated grate links.

The stoker herein described, by employing a deeper fuel bed and a thick layer of refuse near the bridge wall, effectively protects the grate from the heat of the furnace. In addition, full advantage has been taken of the cooling action of the incoming air. The small air spaces and the employment of mechanical draft produce high air velocities and this makes for cool links. An excellent idea of the very different character of the new link for eastern

coal and forced draft is obtained from Fig. 4.

High rates of burning and high furnace temperatures of course subject the furnace brickwork to very severe service. However, the wind-box pressures are low (less than 2-in. water column) and this, combined with the large number of uniformly distributed miniature air openings, causes the impinging flame or blow pipe action to disappear quite near the surface of the fuel bed, thus minimizing to some degree the brickwork deterioration.

The problem of more severe furnace conditions has thus far been met by employing refractories of a higher grade. The side walls and bridge wall have been made with standard 9-in. shapes and the writer is advised that the higher refractoriness of the brick used is in part due to its higher percentage of alumina and its low content of fluxes. Regarding the ignition arch, both the process and the mixture are new in stoker work. The material is highly refractory and porous and its performance under the harder usage bids fair to rival the ordinary arch maintenance in chain grates.

The essential points of this paper have been sufficiently marked to require no summary, but it may be said in closing that those connected with the experimental plant have derived considerable satisfaction in attaining the degree of success noted through the employment of such simple means.

COLOR SCHEMES FOR PLANT PIPING

By H. L. Wilkinson

The importance of some definite and unmistakable means of readily distinguishing between the various pipe and conduit lines and systems in the power plant has long been recognized by both designing and operating engineers. Particularly in large power plants is this question of vital importance, and it should be stated that in some of the well-ordered large power plants reasonably satisfactory systems have been installed. Also there has been some effort made to standardize this practice, a committee appointed by the American Society of Mechanical Engineers to investigate the question having reported upon the preferable distinguishing colours for the various divisions of piping systems in the usual power plant, so states the author at a recent meeting of the American Society of Heating and Ventilating Engineers.

While the importance of standardization in this detail of our power plants has been recognized, too little attention has been given to the matter of late, and the writer believes that its importance should not be overlooked. It is, therefore, suggested that the members of this society consider the following plan which is designed to apply to all piping systems.

It will be noted that the recommendation involves, in addition to piping lines, colour schemes for machinery, motors, hand-rails, dadoes, waste pails, elevator cages, etc., thus extending the usefulness of this distinguishing system to all parts of the industrial plant. It has been a revelation to the writer to find the cordial reception which this proposed colour scheme has received in many industries and concerns of national prominence, and the result is that new industries and concerns are taking it up continually. The application of this standardization might well be extended to the designating by distinguishing colours the tools used in various departments of a plant. This would bring about several benefits. In the first place, it would enable managers to hold each department of a plant responsible for its own tools. Then, because of the improved appearance of the tools, it would create more interest in their care on the part of mechanics. Last, but not least, it would surely be an insurance against tools being carried out of factories.

While the scheme designates definite colours for certain pipes, it is, of course, unnecessary to apply any one particular colour on any one pipe, the arrangement being flexible, so that an engineer may determine for himself his own design. In some cases, where there are as many as fifteen to twenty-five various pipe lines, it is necessary to use combination colours on some pipes, painting the straight pipe one colour and the joints, valves, elbows, etc., the alternating colour. Of course, some exceptions to personal selection will be found where an established custom has been in effect for some time, as in the case of sprinkler-pipes and all fire lines, where vermilion is the logical colour.

The advantage of this standardization will become readily apparent from the case of a certain plant where there was a stoppage or break in one of the pipe lines. The workmen carefully followed the line to the side wall where the trouble apparently existed, and opened up the wall for a considerable area, only to be confronted with everything but the line they sought. Of course the expense of ripping out the wall was nothing compared to the inconvenience and loss sustained, due to the suspension of operation until this repair was made. If this pipe line had been printed with a distinguishing colour and a small arrow placed on the wall where the pipe entered, indicating the direction the pipe took after enering the wall, all this difficulty would have been obviated.

NON-DESTRUCTIVE METHOD OF BELT JOINING

An unusual problem in the handling of hot cement clinkers with a temperature of 200° and over, was recently solved at the plant of the Standard Portland Cement Company, Leeds, Ala., in an interesting and cost-reducing manner. The method decided upon for moving the clinker was a rubber conveyor belt, but the clinker could not be cooled sufficiently in the process previous to conveying, to prevent scorching of the belt and its rapid destruction. The answer to this problem was found by running the belt at an incline of 12 degrees, so that the lower pulley dipped into a trough of water, thus carrying a film of cold water upon the belt, on to which the hot clinker from the loading hopper was deposited.

At this point a new problem was encountered; namely, how to join the belt so that the belt's full strength would be retained, and in a way which would withstand the extremes of temperature, the wear on the pulleys and the abrasion of the clinker. For this purpose Crescent belt fasteners were adopted, because they brought the belt ends tightly together in a snug joint, which made the belt practically endless on the pulley side, so there was no opportunity for clinker ash to get into the joint and abrade the belt ends, and also because in this method of joining, no metal came in contact with the pulleys to cause wear, and a permanent joint was thus assured. Moreover, the exceptional strength of the heads of the rivets and the formation plates prevented destruction of belt joint through abrasion by the clinker.

In six months of operation, this conveyor has carried 61,000 tons of clinker, and the Standard Portland Cement Company credits the saving of $300.00 in belt cost alone to this conveyor. The belt used was Goodyear Hy-temp, which is made particularly to withstand temperatures up to 200°, and is adapted for work on conveying jobs in mines, coking plants and cement factories where heat resistance and ability to withstand hard wear are prime requisites.

One of the most conspicuous forms of British engineering activity since the war lies in the growth of locomotive production. Every country in the world wants locomotives, and the extension of many locomotive shops in both England and Scotland, is designed to ensure that the demand will, as in the past, be met.

It is so far to the good that most of these shops were retained on locomotive work during the war. One firm alone supplied 152 locomotives to British railways, 380 to the French railways, and 300 for other overseas countries during the war. This was in addition to producing many narrow gauge locomotives, hundreds of "Tanks" and hundreds of thousands of shells, numerous aeroplanes, torpedo-tubes, gun carriages, and other "munitions." The total value of the company's output during the war was sixteen million pounds.

The Kelly Foundry and Machine Co., of Goshen, Indiana, have issued their catalogue G dealing with rocking, dumping, and stationary grates. The catalogue is well illustrated, and shows, besides the various types of movable grates, some portable kiln grates, stationary fire bars, and boiler front castings.

Common Sense in Engineering

A Lecture Delivered During the J. E. Aldred Lectures on Engineering Practice at John Hopkins University.

By WALTER M. McFARLAND

(Continued from last issue)

A very important feature in your engineering education and experience is to discover in any specific case the general principle which is involved and which may often be utilized to advantage elsewhere with considerable differences of detail from the original case. A circumstance of this kind came under my observation which illustrates the point quite well.

It was customary in the engines of the Navy up to about the beginning of t so-called "new navy" to make the eccentric straps of brass. Somewhat earlier than this, when steel castings had become available, designers for engines of the merchant service had made eccentric straps of steel castings lined with white metal, the idea being, of course, that the white metal furnished the suitable bearing surface, while the steel casting gave adequate strength. The steam launch on one of our vessels had the eccentric straps made of brass, as usual, half an inch square in cross section, and one of them broke. It was the lower half, which was a half circle with lugs to bolt to the other part. The young engineer who was charged with the repairs did not know of this practice in the merchant service, and having always seen eccentric straps made of brass, tried to make a temporary repair by taking a couple of sheets of one-quarter inch sheet brass, bending them to shape, riveting them together with a few copper rivets and bending over the ends to make lugs for attachment to the other part of the strap. Unfortunately, sheet brass is rather brittle, and, as might have been expected, this temporary strap broke off where the lug had been bent. After trying this a couple of times he was about to give up the attempt at repair and have a new strap made at a shop on shore. Another young engineer on board knew of the practice in the merchant service. It was out of question, of course, to get a steel casting, and it would have been difficult to arange for using white metal, but he remembered the principle of a proper bearing metal to go against the eccentric, backed up by a stronger one to stand the stress. Accordingly he took a piece of half-inch square bar iron, had it bent to shape and faced it with one of the strips of one-quarter-inch sheet brass, securing it to the wrought-iron backing with the copper rivets. This was properly fitted to secure a good bearing, and, of course, worked with entire satisfaction. Later on a new brass strap was secured for use, if necessary, but the repair was so satisfactory that the new strap was never used.

From the circumstances existing in educational establishments it is practically a mater of necessity that in solving problems the data should be furnished you and your work should be chiefly the handling of these data. When you get out into actual practice an exceedingly important part of your work will be the securing of these data accurately, which means that the observations must be made with care and with the aim to be thoroughly correct and reliable. It is not always possible to devise simple checks on the observations which will tell at once whether the records are reasonably accurate, but there are many cases where such checks do exist, and you should endeavor, if possible, to ascertain what such checks are. Some will come from previous observations and experience, some from study, but a great many will be a matter of common sense. A striking case which came under my observation and where common sense was the check is worth telling.

Most of the Mediterranean ports are protected by breakwaters so that the water inside is smooth, and as a result when coal is brought off to vessels it is in rectangular piles on flat scows. Unfortunately, coal dealers in the Mediterranean have a rather bad reputation for trickery. Consequently, in naval vessels when coal is taken on board great care is used in measuring the coal piles so as to be sure of the amount received. I was attached to a vessel which called in the harbor of Algiers. A couple of our midshipmen were detailer to measure the coal piles which were, roughly, 40 feet long, 20 feet wide, and between 5 and 6 feet high. At the end of the first day they handed in figures to show the amount received, which came to 375 tons. The executive oicer of the vessel had been attached to her for some two years, and so was familiar with the rate at which coal could be taken in. He said at once that some serious mistake had been made for the reason that never before had more than 300 tons been received in one day, even when the conditions were better for rapidity than existed at Algiers.

The midshipmen were told to go over their work again to see if there was any mistake, and they examined their computations but could find no error. I was the possessor of a slide rule, and was, therefore, supposed to be something of a expert on figures, and was called in to see if I could find what was wrong. I had had nothing to do with the coaling, but was on board during the day, and happened on several occasions to notice the young men while they were making their measurements. I checked up some of their arithmetical work and found it was correct, so it seemed that the trouble must be in the measurements themselves. I remembered that when I saw them making the measurements the particular piles on which they were working did not come above their heads, while I noticed a great many heights recorded as being over six feet. The solution of the difficulty then occurred to me at once. They had used one of the tape measures from the engine room. If you do not know it now you will learn by experience that the ordinary linen tape measures are fitted with a brass ring in the end for convenience and to prevent the tape from slipping into the case. These rings are invariably torn off after a relatively short service, and the common practice is then to tie a knot in the end of the tape and to make all measurements from the 1 foot mark. I asked the midshipmen if they had used the linen tape, and found they had. It appeared on further investigation that the man who held the knot recorded the figures, which were caled off by the man at the other end. The recorder assumed that the other man had deducted one foot before calling off the measurement, while the man at the other end called off what he saw, assuming that the recorder would deduct one foot. There would have been no easy way to check this on the measurements of 20 feet and 40 feet, but obviously it was absurd to put down heights of 6 feet 3 inches and 6 feet 6 inches when, as a matter of fact, they were looking over the piles. Remembering that when I saw them the piles were below the tops of their heads, I asked them if there were any piles which they could not look over. On reflection they said that there were none. I asked then where they got their heights of over 6 feet, and at once the error developed that every measurement they had made was one foot too great. When the correction was made the amount of coal received was only 275 tons instead of 375.

As you hear the story you may think that these young men were unusually stupid. As a matter of fact, this is not true at all, and both have since made enviable records in the navy. They simply failed to use common sense in applying the obvious check as to height when they could look over the piles of coal, which should have at once have called their attention to the carelessness with which they were making the measurements.

While speaking of this subject of checks on observations you will in time

acquire a great many of these from practice and experience, and it is well to do so as soon as possible. For example, with good average coal of, say, 14,500 B.t.u.'s pepr pound, if all the heat went into the formation of steam (that is 100 per cent. efficiency) you would have evaporation from and at 212° F. of about 15 pounds. Likewise, with good quality fuel oil of, say, 19,500 B.t.u.'s the corresponding evaporation would be about 20 pounds. These are figures easy to remember, and when you remember in addition that the best average results in good boilers are about 75 per cent. efficiency with coal and from 80 to 82 per cent. efficiency with oil, you will be in a position to discourage fairy tales about remarkable performances in the way of boiler efficiency. It is the custom now in all carefully-conducted boiler tests to tabulate what is known as a "heat balance," showing the way in which the heat in the fuel is distributed. Two elements of loss which are present in every fuel are the heat carried away in the dry chimney gases and the loss due to moisture formed by the burning of hydrogen. The sum of these two losses at moderate rates of combustion is, roughly, about 15 per cent. in the case of coal, and about 14 per cent. with oil fuel. You will see at once that if all the other losses are eliminated the possible efficiencies would be only roughly some 85 per cent. Consequently, if figures are shown you indicating an evaporation of 13 or 14 pounds of water per pound of coal, or 18 or 19 pounds of water per pound of oil, you will know at once that these results are impossible. Either there has been excessive priming of the boiler or there has been an error in the observation of the amounts of fuel and water.

Some years ago a friend of mine who is a very able engineer was discussing the matter of what is known as "surface combustion," where the gassified fuel passes through a porous earthen plate and burns on the surface. He asked if I had gone into the matter carefully, and I told him that while I had read something about it, I did not know very much. He then went on to say that it was a matter of the very greatest importance because the efficiency with this method of combustion was claimed to be five or six times as great as by any other method. I reminded him at once that this was absurd because a good average performance with oil fuel gave 80 per cent. efficiency, and five times this would have been 400 per cent., which was, of course, ridiculous. He then concluded that the ratio of five or six times referred to the efficiency of an open grate or some other similar very inefficient method of burning coal.

While as engineers we always want our work to be accurate, common sense teaches us that there is a time for everything, and there are often occasions where you want to reach a decision quickly and where approximate data will be just as useful as those which are absolutely accurate. You will find as you go along that there are a number of "thumb rules" or "round figures" which are very convenient to carry in your memory for just such occasions. For example, a square foot of sheet steel one inch thick weighs approximately forty pounds, which gives you a "round figure" easy to remember and easy to divide for sizes which you are likely to need. The error is only about 2 per cent. Again, one foot in length of a tube four inches in diameter gives one square foot of surface, and two feet long of two inches diameter, and four feet long of one inch diameter. Here the error is a little greater, being about 4 per cent.

There is another convenient figure to remember at the present time—when the question often comes up as to whether it will pay to change a coal-burning installation to one using oil. If you will take the relative thermal values of oil and coal and allow for the higher efficiency when using oil than coal, which is, roughly, about 10 per cent. of the efficiency with coal, you will find that the cost for the same thermal value of fuel may be expressed as follows:

When the price of oil in cents per gallon is half the price of coal in dollars per ton (of 2,240 pounds) the cost for the fuel only is the same. In other words, two-cent oil costs the same as $4 coal. There are economies in using oil due to a smaller boiler-room staff, the absence of ashes and other things, which must be considered, but this "thumb rule" will often enable you to say whether the step is worth considering at all. For example, if oil is selling at five cents a gallon while coal can be obtained for $5 a ton, it is perfectly evident that the difference in the cost of the fuels is so great as to make it unwise to change. If, however, oil, say, is four cents a gallon and coal $7 a ton, the difference is then so small that it is possible the other savings would justify shifting over to oil, so that it is advisable to make a detailed investigation.

From one point of view the talk that I have given you may be regarded as rather disconnected, because so many subjects have been considered, and yet the same theme runs through them all—the application of common sense in the solution of engineering problems. Perhaps the very diversity of the subjects may impress you all the more with the great importance of common sense.

My aim has been to encourage you to develop and trust your own common sense by showing how it applies everywhere and is of the greatest service. Indeed, without it great mental ability is often helpless or goes wrong. One of the most brilliant engineers whom I know, who has designed some of our most important electrical machinery, and who is an accomplished scientist, once said "nine-tenths of good engineering is common sense." And, in closing, let me say again that common sense is not a special gift and does not replace careful study, but it does mean the application to the problem at hand of your best experience and judgment without prepossession or prejudice.

COPPER-ALUMINUM-IRON BRONZE AS AN ACID-RESISTING ALLOY

By O. L. Kowalke

Copper-aluminum-iron bronze is known to possess many valuable qualities. In tensile strength it ranks with mild steel. It can be forged while hot, and also rolled into sheets; it can be machined to a nice finish, and sound castings can be made of it, free from shrinkage-holes and blowholes. These among other qualities render the alloy suitable for bearings and gear. But very little has hitherto been known concerning its acid-resisting properties. With a view to acquire knowledge in that direction, a systematic series of tests have been made at the University of Wisconsin laboratories. The results of these tests, which were made with various acids and alkalies, are set out for detailed comparison in three tables. Only two of the bronzes experimented with are reported on; they are distinguished as A and B. Their average compositions and properties were:

	Bronze A	Bronze B
Copper	87.0 %	85.6 %
Aluminium	9.8 %	10.8 %
Iron alloy	3.14 %	3.57 %
Ultimate unit stress	74,800 lb. sq in.	66,600 lb. sq. in.
Reduction in area	19.0 %	13.0 %
Elongation in 2 in.	21.0 %	11.5 %
Specific gravity	7.71 %	7.58 %

The specimens for the corrosion tests were approximately 1 in. by 0.07 in., and were finished smooth, with square edges. Most of the tests were made at room-temperatures of 72 deg. F. and 85 deg. F., but a few were made at 194 deg. F.

Bronze A was found to be resistant to several acids, particularly to sulphuric, lactic, phosphoric, tartaric, and acetic acids. Nitric acid attacked the metal readily, the concentrated acid acting violently. Hydrochloric acid and ammonia solution both attacked the metal too readily for commercial purposes. Caustic soda had but little effect. In the case of bronze B, a strikingly higher resistance to sulphuric acid is shown. Also ammonia did not corrode it so readily as bronze A. Nitric acid attacked bronze B also too readily; and hydrochloric acid attacked it more readily than bronze A. It is interesting to note that the corrosion, in 35 per cent. sulphuric acid, of a forged specimen of bronze A is only about half that of the rolled-sheet and cast forms.

The Illinois Stoker Company, of Alton, Ill., have issued a catalogue "L," describing their natural and forced draught type of mechanical stokers. These are of the chain-grate type, those for natural draught being type A, and the force draught, type G. A preface is included, showing the advantages of mechanical over hand firing, and following this is a well-illustrated section descriptive of the two types. At the back of the book is a description of the Illinois arch, and a chapter on boiler and furnace efficiency, including several diagrams.

Some Useful Information on Gauge Glasses

The Various Troubles to Which They Are Subject Are Discussed Also Means of Preventing Some of Them—The Right and Wrong Way of Fitting a Glass is Explained

By H. E. WAVERLEY

THE glass water gauge, which is such a familiar object and may be seen on almost every boiler front, may be considered a time and labor-saving device, and to a certain extent a safety appliance also. The glass gauge, like other safety appliances, must be kept clean and in good condition at all times in order to ensure reliable indications of the water level in the boiler. It is a simple device to keep in order, and not a difficult one to repair when it gets out of order. Where raw feed-water is employed, as is generally the case where boilers are not used for power purposes in non-condensing plants, the gauge glass should be kept clean by blowing out at regular intervals. The interval between cleaning-out times depends upon the quantity and the quality of the water used. Muddy water deposits a sediment, principally mud, while clear water deposits carbonate and sulphate of lime and magnesia which form scale.

When closing the valve after blowing out the column and glass, a certain quantity of water carrying deposits is retained in the column and glass, and in a few minutes these settle along the bottom of the lower column pipe and in the bottom connection leading to the glass. If the blow-off valve be now opened a very little and for about 5 seconds these accumulations may be removed before they have had an opportunity of becoming attached to the surfaces, and without renewing the entire contents of the column and glass. By a careful manipulation of the blow-off valve under the water column, and of the drip-cock under the glass, these parts may not only be cleaned of sediment but they can to a considerable extent be kept free of such troublesome accumulations. Where the feed-water is very bad and the amount of sediment is found to be large, it always pays to be very careful when blowing out the column and glass, and to remove as much of the deposits as possible, not because of the trouble that would otherwise be experienced in removing hard scale, but to ensure accurate indications of the water level at all times and upon which the safety of the plant very largely depends. The glass water gauge in many plants is relied upon almost entirely from one week's end to the other, the gauge cocks being used in emergencies only. It is nothing more or less than criminal negligence to place so much confidence in a glass water gauge unless great care is taken to ensure its proper condition at all times, and that can only be done by frequent and thorough cleaning.

In certain works on steam engines and boilers directions are given for the proper care of the water column and gauge glass. The directions are generally to the effect that the glass should be blown out from four to six times each day, and that the gauge cocks should be tried at least once every half-hour. These directions are decidedly on the safe side in one respect, and that is that a gauge-cock cannot possibly clog or become scaled over during a single half-hour, and with the worst possible feed-water and condition of boiler. On the other hand, experience with different firemen and water tenders seems to indicate that the directions if followed to the letter eventually lead to dangerous conditions.

It must be understood that there are exceptionally careful men to be found in boiler-rooms, and there are water columns fitted with exceptionally good gauge-cocks and water gauge connections. The directions referred to are all that can be desired when these exceptional conditions exist, but under ordinary conditions the very frequent use of these important devices produces needless wear and a large amount of avoidable labor and annoyance. Gauge-cocks cannot be expected to remain steam and water-tight for many weeks when used twice an hour day after day, and when they begin to leak at very short intervals and spatter mud and water over a nicely kept boiler front the temptation to plug them, or to repair them and then neglect to use them often enough to ensure safety, is indeed very great, and too often proves irresistible. The moderate use of gauge-cocks is all that is necessary to ensure safety, and it further ensures the continued use of the gauge-cocks without leakage or other inconvenience.

Gauge glasses as a general thing break oftener when frequently blown out. There is a practical limit to the frequency with which the glasses should be blown out the same as with the opening of gauge cocks, and the limit depends upon the frequency with which the boiler is cleaned, the kind of water used, and the kind of glass gauge fittings employed. With fittings having liberally proportioned openings leading to the glass, say, not less than ¼ inch in diameter, and when the boiler is cleaned every two weeks or after 135 hours' run, four times a day is often enough to blow out the glass, and three times a day is often enough for the water column. A day is assumed to be the length of time necessary to prepare for a day's run of ten hours, and to prepare the machinery for the night after shutting down.

Glasses last anywhere from two minutes to two years on power boilers, and frequently as long as three years on boilers used for low pressure heating. Probably three or four months would be a fair average for power boilers carrying pressure of 100 pound and upward. Glasses used on power boilers are generally blown out much oftener than the glasses on heating boilers, especially in non-condensing plants. The effect upon the glass of frequent blowing, and consequently of frequent heating and cooling, is similar to what is known as the fatigue of metals. After expanding and contracting rapidly a certain number of times the glass will fail. If such a glass lasts 24 hours it will generally last a month or more. When the packing, which is soft and pliable at first, becomes dried out and hard as it will in the course of a month or two, the glass is more apt to break because it is not as free to expand as it was when the packing was first put in, and this, together with the alternate heating and cooling and the gradual wearing away due to blowing out the glass, tends to greatly shorten the life of gauge glasses when used on boilers supplying high-pressure steam.

When condensed steam is fed into the boiler, or gravitates into it from the heating system, very little deposit and accumulation of scale occurs, and the water is generally clear and of course does not tend to obstruct small passages quickly, so that the gauge cocks are seldom used, and the gauge glass is blown out at rather long intervals. Glasses last much longer under the latter conditions.

The gauge cocks should be used to check the indications of the glass each time the latter is blown out. It is important to have the fittings exactly in line with each other, and to have them large enough so as not to cause the glass to bind or to be cramped in the least. When the fittings are not in line the glass is apt to be cramped either when putting it into the sockets in the fittings or when tightening the packing nuts. When tightening the nuts around a glass when in the position indicated in Fig. 1, the tendency is to straighten the glass—that is, to bring the glass into a position parallel to the socket at the end being tightened, and this tends to bend the glass, as shown in Fig. 2. It is, of course, impossible to bend the glass consequently the glass either snaps when the nut is turned or when the glass expands when it becomes heated. Failure to notice these little points is responsible in many cases for continued annoyance from breaking gauge glasses.

Sometimes it is necessary to ream out the fitting, say 1-32-in. or 1-16-in. larger so as to give the glass sufficient free-

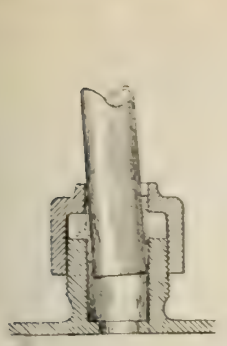

FIG. 1.

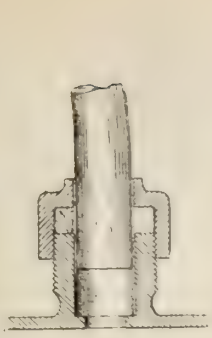

FIG. 2.

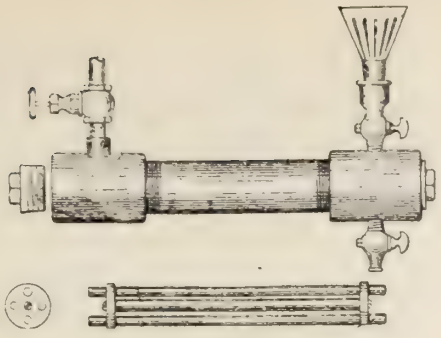

FIG. 3.

dom. Wrenches should almost never be used for tightening the packing nuts around the gauge glass. When a glass is packed with the proper kind of packing and the nuts have been screwed up just tight enough to prevent leakage when both the glass and the packing have been warmed, the glass may readily be turned around in the fittings with merely the thumb and forefinger.

After putting in a new glass turn on a very little steam, leaving the drip at the bottom of the glass open so that the steam will gradually fill the glass and escape through the drip cock. The glass is thus warmed thoroughly before the water is let into it and before it is subjected to pressure. When the glass has become thoroughly hot, open the steam valve wider, then open the water valve a like amount, and continuing to open both valves alike until fully open, then slowly close the drip at the bottom. This method not only allows the fittings to be thoroughly blown out, but enables the operator to increase the pressure on a new glass and new packing more gradually. The drip-cock should now be opened and closed suddenly. If the fittings are filled with sediment to such an extent that sudden opening and closing of the drip-cock is necessary to clear it, it is evident that the drip is not opened often enough, or that the boiler is extremely foul.

When the drip has been closed for some time the water in the glass will become comparatively cool which is due to the absence of circulation, while the upper part of the glass will become comparatively hot. As this change of temperature in the low end of the glass takes place very slowly, no trouble is experienced, but when the drip is opened suddenly and the steam is thus brought in contact with the cooler end of the glass the latter very frequently breaks, and when that is the cause of breakage the glass will nearly always fail at some point below the middle, and generally about one-third the length of the glass from the bottom.

It frequently happens that an entire package of gauge glasses will prove to be too hard and brittle, and that the entire number will break within a few minutes after putting them in. It is due to experiences of this kind that many engineers have been led to anneal all the glasses before using them. This is generally accomplished by means of a water and steam bath, the water and the glasses being heated by steam. Engineers generally rig up some apparatus with what old material they have on hand that will accomplish the purpose. A simple device that has given satisfaction for this purpose is illustrated in Fig. 3.

It consists of a short piece of 2-in. or 2½-in. pipe about 4-in. longer than the glasses. On one end is screwed a coupling with the outer end plugged, and a drip-cock screwed into the upper and lower sides. On the other end is a reducing tee, which is plugged at the outer end, and a ½-in. or ¾-in. pipe screwed into the smaller opening at the side. A valve is placed in the smaller pipe close to the tee. The vertical pipe is connected to the boiler or to one of the steam pipes. A rack made of wood is provided having suitable holes in both heads for the gauge glasses; the rack serving to keep the glasses away from the pipes.

The plug is removed, as shown, and the rack containing the glasses slipped into the pipe. The plug is then screwed in and the pipe filled with water of the same temperature as the air in the room. Both cocks being closed, the valve is opened and the condensed steam in the vertical pipe, which is practically cold, is admitted into the remaining space in the 2-in. pipe and connections. The lower drip-cock is then opened a very little thus permitting the water and condensed steam to gradually work out, which admits steam and heats the pipe and the glasses very gradually. When steam issues from the lower cock the valve is opened wide, the cock serving to keep the pipe drained. The glasses are then kept under boiler pressure, and consequently at boiler temperature for from three to four hours. At the end of that time the lower cock is closed, when the pipe at once begins to fill with hot water, the water cooling down very gradually owing to lack of circulation as the vertical pipe becomes filled. When the pipe has cooled to its original temperature the valve is closed and the two cocks opened thus draining the pipe. The plug is then removed and the glasses taken out, dried, and put away again in the box.

Glasses treated in this way have given the best of satisfaction on high-pressure boilers where the change of temperature when blowing out is very great, and where glasses are subjected to draughts of cold air, and also for portable and hoisting engine boilers, which are subjected to rather severe usage, as far as changes of temperature are concerned. Any other device which will permit the glasses to be heated very gradually and again cooled very gradually will serve the purpose fully as well as the one just described.

The bursting of gauge glasses is attended with not a little personal danger and discomfort, and it is important that all reasonable precautions against such breakage be taken by the person in charge. When a gauge glass breaks when under pressure always close the lower valve first. It is cheaper in the long run to cut glasses with a gauge-glass cutter than to attempt to cut or break them off with a broken file, or by similar means, because a slight nick in the glass at the wrong place may mean the early destruction of the glass when subjected to pressure and varying temperature.

There are other practical means for preventing the breakage of gauge glasses. Some engineers fit a thin brass or copper thimble into the upper end of the tube, as shown in Fig. 4, which prevents scale and water from coming in contact with the glass when blowing out the latter, and hence it reduces the eroded and pitted appearance commonly seen at the upper end of unprotected glasses. Tubes made of aluminum may be obtained of dealers in engineers' supplies which accomplish the same result.

These tubes and thimbles, it will be seen, protect the inner surfaces of the glass only, and as the glass is liable to be crowded to one side or the other in the packing nut as well as in the fitting itself, it is a good plan to also protect the glass on the outside. A simple means of protecting the glass on the outside is also obtained from dealers in gauge glasses.

It consists of a rubber sleeve adapted to slide over the end of the glass, as shown in Fig. 5. The glass cannot come in contact with the socket in the fitting, neither can the packing nut touch the glass when the packing is screwed up. The combination of the thimble and the latter device prevents the rapid wear of the glass at the top, and also retains the glass clear of all metallic contacts which has been found to be very desirable where glasses are subjected to high pressure and temperature and sudden changes in the latter.

When the rubber protector is employed separate packing rings are not needed, because the packing forms a part of the sleeve as shown. Annealed gauge glasses protected inside and out by this or similar means will last as long under any circumstances as it is possible to make them by any means thus far made known.

Many engineers suffer unceasing annoyance due to breaking gauge glasses because they do not pack them with the proper material. Candle wicking and asbestos wicking should be used only in case of emergency. The latter materials are too porous and require too much

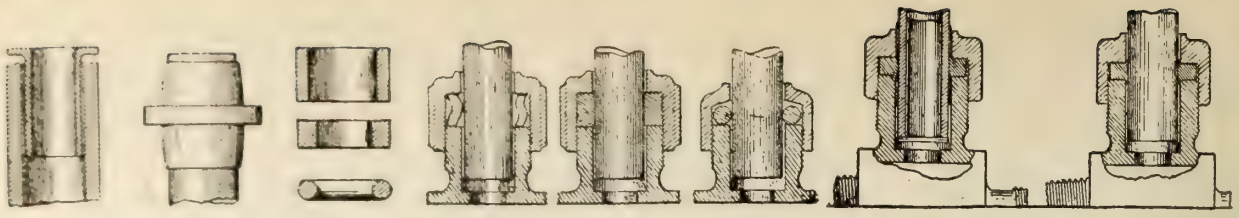

FIG. 4. FIG. 5. FIG. 6. FIG. 7. FIG. 8 FIG. 9. FIG. 10. FIG. 11.

pressure in order to make a tight joint to be suitable for packing a glass tube of any kind. The wicking soon becomes charred and hard and begins to leak, and it is evident that after it becomes hard it is useless to attempt to tighten the packing nuts. A second tightening merely serves to compress the glass so tightly as to prevent the necessary expansion, and the almost invariable result is breakage.

When a gauge glass is packed with wicking, either candle wicking or asbestos, and begins to leak at the end of, say, a month, the best thing to do is to repack the glass. Tightening the nuts on hard, dry packing, especially on an object so delicate as a gauge glass, avails nothing in the long run; but, on the other hand, it does add immensely to the number of glasses broken in a given time. Soft-rubber rings of the proper size are by far the best, and consequently these rings furnish the cheapest means of packing gauge glasses. The first cost of rubber is merely a trifle greater than that of wicking, while the life of the packing is more than doubled, and the number of glasses broken is greatly reduced.

Rubber rings are made in three forms or shapes when referring to cross-section —viz., the thimble, the square ring, and the round ring. These are shown in Fig. 6. Which of these three shapes will be found the more serviceable will depend upon how they fit the packing nut. Gauge-glass fittings are made of a variety of designs, some having a wide but shallow space to receive the packing, while others have a narrow and deep chamber between the sides of the nut and the glass. It is evident that the same form of packing cannot well be used equally well with all forms of packing nut. That is getting details down rather fine, but it is well worth considering when we remember that the durability of the glass and the safety of one's eyes depend largely upon the manner in which this work is done.

The packing ring should be of such size and shape that one ring only at each end of the glass will be required. A good job of packing gauge glasses can seldom be done when two or more rings are employed. When a rubber thimble is used on a packing nut adapted to the square ring, the result is about as shown in Fig. 7. This may be exaggerated a little, but it serves to illustrate the principle. The rubber thimble is particularly well adapted to the style of nut illustrated in Fig. 8, because the space between the nut and the glass is of the same shape, and is nearly the same size as the ring. The ring in this case is merely compressed lengthwise, and this becomes wider without any tendency to buckle or double up.

If fittings are used having a wider space for the packing, either the square or round rings give better satisfaction. The round ring is particularly well adapted to fittings having bevelled edges and nuts as shown in Fig. 9. The inclined surfaces are supposed to assist in crowding the packing against the glass, and perhaps they do, but as a general thing the bevel or angle is so slight that it is doubtful whether it is of much assistance in making a tight joint. When the edges of the fitting and nut are square, the square packing ring is best adapted, as shown in Fig. 10.

When two rings are employed the result is very apt to be similar to that shown in Fig. 7, on account of the yielding nature of the rings, and this is especially so when both rings do not fit the nut perfectly, one ring tending to crowd the other away from or against the glass, thus rendering one of the rings practically useless, and the other one less efficient. A glass packed with a protector ring, and also protected on the inside is shown in Fig. 11. It will be seen that this is an ideal arrangement when the water is muddy and the glass and water column have to be blown out frequently.

There may be found on the market at a reasonable price rubber packings adapted to every construction for gauge glass fitting regularly made; also highly annealed glasses under various trade names, and after considering the subject as thoroughly as its importance demands it will readily be seen that in order to secure a tight joint with the least possible pressure, thus avoiding any tendency to break or to cramp the glass due to the packing, it is necessary to obtain a form of packing that will fit snugly in the space in the nut.

To get the best result from gauge glasses in any service first procure a good glass, then get suitable packing and keep it in a cool, dry place so that it will not harden. See that the fittings are in line, then pack the glass and screw up the nut with the fingers only. If the glasses break frequently, try some means for protecting them inside and out, and also anneal the glasses, which may be accomplished in the manner previously explained. A little more careful attention to the seemingly insignificant detail in a steam plant will be the means of saving a great deal of needless annoyance and not a little danger of personal injury.—"Southern Engineer."

A REMARKABLE RUBBER DISCOVERY

A discovery of the highest importance has been made by a lecturer in chemistry at the Manchester (England) School of Technology. When rubber and sulphur are mixed together at a high temperature the rubber becomes hard and tough—"vulcanized" is the technical term for the change. While rubber can stand the necessary heat, other raw material with which it might be usefully mixed would be destroyed. The new invention is a cold process, in which two gases are used to produce the free sulphur required in vulcanising. When crude rubber, either in the solid or the liquid form, is treated with the two gases it becomes efficiently vulcanized, and when it is mixed with any waste material such as sawdust, leather scraps, or paper, a similar change takes place without the properties of the waste material being affected. This discovery is to be applied immediately to the manufacture of linoleum, the heavier classes of wallpaper, and artificial leather for upholstery. It is also applicable to the manufacture of one-piece boots (of rubber and leather scrap) and of felt (combining rubber and "shoddy").

ANOTHER FIRM TO BUILD DIESELS

The Worthington Pump and Machinery Corporation have issued a bulletin announcing their entry into the marine Diesel engine construction field. The bulletin reviews the marine situation and the case for the Diesel internal combustion engine, and quotes instances of actual working to demonstrate the reliability of this prime mover. The announcement of the building of a 2,400 I.H.P. six cylinder marine Diesel by the company follows. This engine was built at the company's Snow Works, Buffalo, and the cylinders are 29 inches bore by 46 inches stroke, and the crank shaft makes 120 revolutions per minute, the engine being of the 4 cycle type. The engine is built to the Worthington Company's own designs, but the leading features of successful foreign builders have been incorporated. The company have made plans to enable them to produce these engines in large numbers as the demand increases.

The Theory and Practice of Electricity

In These Articles the Theory Will be Developed Sufficiently to Enable the Practical Man to Grasp the Underlying Principles of Apparatus Under His Care, Both Direct Current and Alternating

W. F. SUTHERLAND

MAGNETISM and electricity are so intimately related that one can hardly be studied without the other. In the earlier days of electrical science this relation was not so apparent and it has only been during the past century that the true relationship has been worked out. From the study of these things indeed the whole electrical industry of to-day is largely based.

In the last lesson it was seen that the lines of magnetic force around the poles of permanent magnets could be visualized by means of iron filings. If we now take a piece of cardboard and passing a heavy wire through it cause a current to flow through the wire; by sprinkling the cardboard with iron filings we shall see the filings arrange themselves in concentric circles around the wire, much as is shown in Fig. 22.

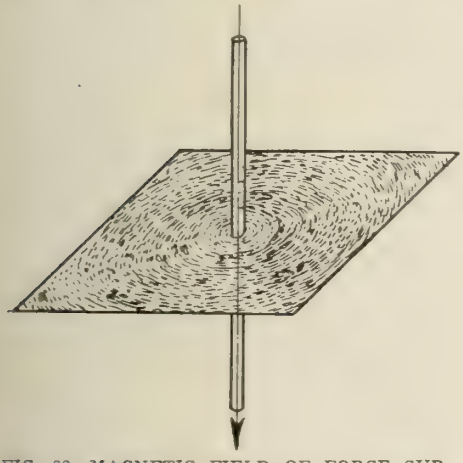

FIG. 22—MAGNETIC FIELD OF FORCE SURROUNDING A WIRE CARRYING CURRENT AS SHOWN BY IRON FILINGS.

This will give rise to the suspicion in our minds that the electric current exerts some kind of force upon the field of space around the wire through which it is passing and from the behavior of the filings we will naturally conclude that some form of magnetic force is present. This is the case, although a difference exists between the magnetic fields of magnets and wires. In a permanent bar magnet the lines of force emerge at one end and enter at the other, while in a wire carrying current the lines of force surround the wire.

If instead of filings we use a compass as in Fig. 23 and move it around the wire on its cardboard support we will find that the needle changes its position and any point on it will trace a circle around the wire, the needle always pointing in a direction tangent to a circle drawn through its centre. Examination will show that the magnetic force gets bigger as the current increases, disappears when the current stops and reverses if the current is reversed.

Direction of the Magnetic Flux Due to Current

From the behavior of the needle when the current is reversed, it may be suspected that the direction of the current has quite an effect on the direction of the magnetic lines of force surrounding the wire. In Fig. 23 if the wire is carrying current in the direction indicated by the arrow at its lower end, then the needle will come to rest with the north pole pointing out at the observer. If the current is now reversed and made to flow up through the wire instead of down, the compass needle will immediately swing around and point with its north pole away from the observer. In the first case the lines of force are said to travel around the wire in the direction shown by the arrows on the two circles.

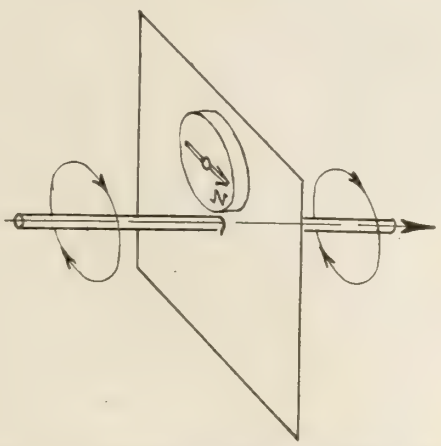

FIG. 23—MAGNETIC FIELD OF FORCE SURROUNDING A WIRE AND DIRECTION OF FLOW.

The direction which the lines of force will take may be easily remembered by thinking of a right hand nut and screw. If the nut is turned over to the right on the screw it will travel away from the observer. The direction of rotation of the nut corresponds to the direction of the magnetic lines of flux, while the travel of the nut along the screw indicates the direction of current flow.

The relations between current flow and magnetic flux are also easily remembered by another simple little rule shown in Fig. 24.

The right hand is supposed to grasp the wire with the thumb extended along it in the direction in which the current is flowing. The fingers of the hand will then wrap around the wire in the direction in which the magnetic flux is travelling.

The Solenoid

If we take a coil of wire and thread it through a piece of cardboard as shown in Fig. 25, then pass a current through it and sprinkle iron filings on the cardboard, a figure will be obtained much as is shown. The filings will arrange themselves in an orderly pattern. Some of them will group themselves in little circles around each individual wire, but the majority of them will group themselves in lines passing around all of the wires in through along the axis of the coil and around to the outside. It will be seen that the figure has some resemblance to that made by a permanent bar magnet and we have actually produced a magnet though perhaps weaker and of no consequence. If the current is interrupted the filings will lose their orderly arrangement and will show no indication of lines of force.

Magnetic poles are formed in the same way as with the permanent magnet, at the ends of the coils. The reason for this may be better understood from Fig. 26. Here a small coil is shown in section with the top part cut away. The current is travelling in the direction indicated by the arrows and the magnetic lines of force around each wire, indicated by the circles have the directions shown. In the top half of the diagram the flux will travel clockwise since the current is flowing away from the observer, while in the bottom half they will be seen to travel in the opposite or counter-clockwise direction since the current is flowing towards the observer. By applying the right hand rule given above this will be seen to be so. Instead of the magnetic flux, due to each wire passing around the individual wire, the greater portion of it will flow around all the wires and we will thus have a strong stream of magnetic flux passing through the coil emerging at one end and entering again at the other.

If a bar of iron is placed in the centre of the coil of wires shown in Fig. 25 the magnetic effect will be found to be very much increased. As stated in the last issue of Power House, some materials have the property of offering much less resistance to the flow of magnetic flux than others. Iron in some of its forms is one of the best conductors for magnetism and its insertion into the magnetic circuit lowers the magnetic resistance appreciably. Thus supposing we have the same coil and the same flow of current through it the force causing the flow of magnetic flux will be the same, but since the magnetic resistance,

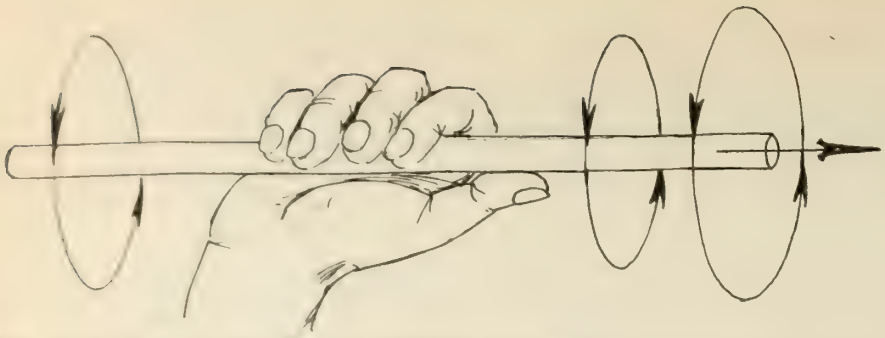

FIG. 24 RULE FOR DETERMINING DIRECTION OF MAGNETIC FLUX AROUND WIRE CARRYING CURRENT.

if it may be called such, will be much less, a greater effect will be produced.

There is a limit to the amount of magnetic flux which can be forced through iron or rather it becomes more and more difficult to increase the strength of any electro-magnet after a certain point is reached. In many problems it is important to be able to express the amount of flux as a numerical quantity and a unit has been chosen for this purpose called the Maxwell. This name is somewhat out of use at present and instead of saying so many Maxwells, it is more usual to say so many lines of force. The flux density or the strength of the magnetic field is measured in lines of force per square centimeter or per sq. inch. This unit finds considerable use in the design of electrical apparatus. Iron and all other substances which are magnetic have the peculiarity that when magnetized to a high flux density the permeability or capacity for further magnetization greatly decreases. Under such conditions the magnetic material is said to be approaching saturation and with very high flux density is said to be saturated. Saturation is rather an indefinite term. With good wrought iron or steel it would be reached at something like 20,000 or more lines per sq. centimeter, while in cast iron it would be in the neighborhood of 8,000.

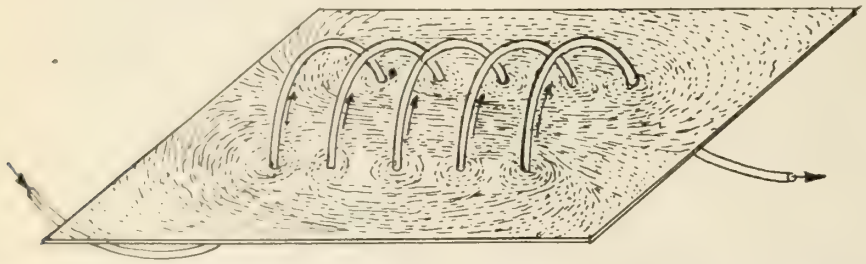

FIG. 25—THE MAGNETIC FIELD OF FORCE SURROUNDING A SOLENOID AS SHOWN BY IRON FILINGS.

In Fig. 24 a method of determining the direction of flow of magnetic flux around a wire carrying current was shown. Fig. 27 shows a corresponding method of determining the polarity of solenoids or electro-magnets. In this case the coil of wire is grasped by the *right* hand with the fingers pointing in the direction of current flow. The thumb extended along the coil will point in the direction of the magnetic flux and since the flux flows out of the north pole the thumb will also point towards the north pole of the magnet or solenoid.

In the next issue of Power House the elementary theory of dynamo-electric theory will be discussed.

Uehling Instrument Co., 71 Broadway, New York, has just issued Bulletin No. 111 describing style U Uehling CO_2 equipment. This is a new design built in single and multiple forms, the latter serving any number of steam boilers simultaneously, up to a total of six. The purpose of this equipment is to save fuel by burning it with the proper air supply. Neglect of this factor is costing power plant owners heavily. Among the notable features of the new machine are speedy action, resulting from a new form of aspirator, absence of chemical solutions, greater simplicity and the unique plan of providing an auxiliary boiler front CO_2 indicator, which guides the fireman, while the CO_2 recorder, installed in the chief engineer's or superintendent's office, makes a continuous (not intermittent) record, showing all changes in boiler adjustments that are conducive to either waste or economy.

The Uehling Instrument Co., 71 Broadway, New York, manufacturers of fuel economy equipment, announces that it is now being represented in the New England states by the Smith Engineering & Supply Company, 89 State street, Boston, Mass., manufacturers' agents and engineers, specializing in power plant equipment. Mr. S. W. Smith, president of the latter company, was until very recently associated with the Uehling Instrument Company with headquarters in their New York office.

Starting Properties of D. C. and A. C. Motors

The Various Characteristics of Different Types of Motors Discussed in Relation to Their Starting Properties—Paper Read Before the London Branch of the Association of Mining, Electrical Engineers

By O. L. RECORD

ONE has often to decide what type of motor is best suited for a particular purpose, and consequently a few notes on motor characteristics, with special reference to their starting properties, may be useful.

Direct-Current Machines

(a) Series-wound.—In this type of machine, as the field is excited by the main current, an increase of load increases the strength of the field, and so slows the machine down, and vice versa.

As the torque is proportional to the product of the armature current and field strength, the torque of a series motor would always vary directly as the square of the current were it not that the magnetic circuit becomes saturated above a certain point. In such a theoretical case, doubling the current would give four times the torque, and, at the same time, the speed would be halved, so that the motor would deliver double the power at half the speed. In practice one would obtain considerably more than double the torque and rather more than half the speed.

The curves in Fig. 1 give the relation between current, torque, speed, and power on a typical motor of this kind. It will be seen that the motor automatically adjusts itself to the load, taking a heavy load at a low speed and a light load at a high speed. At starting the torque will be proportional to the current taken, the motor giving full-load torque with full-load current, the latter being limited to the value required by a series starting resistance.

(b) Shunt-wound.—In this type of motor, as the field is excited by a circuit separate from that of the armature, the speed is independent of the armature current except for a slight drop on heavy loads, due to armature resistance voltage drop, and it depends merely on the field current, which again is proportional to the supply voltage. By varying the excitation the speed can be altered quite independently of the load. For a constant field the torque is proportional to the armature current.

Fig. 2 gives curves of torque, speed, and power for this class of motor, and it will be useful to compare this with Fig. 1. In this class also the starting torque will be proportional to the current taken, the motor giving full-load torque with full-load current, and the latter being limited to any desired value by means of a series starting resistance.

(c) Compound-wound.—The effect of the compounding is to give increased starting torque for the same starting current, but at a somewhat lower speed, depending on the proportion of series turns, and also to increase the momentary overload capacity of the machine. On the other hand, the difference in speed between no-load and full-load will be increased.

If even greater constancy of speed is required than that given by a shunt machine, this may be obtained by having a few turns of series winding arranged in opposition to the shunt winding, so that as the load is increased the field is weakened and the speed kept up. This arrangement, however, makes the starting up more difficult, and also decreases the overload capacity of the machine.

Figs. 3 and 4 give the torque, speed, and B.H.P. curves for a compound-wound motor, with cumulative compounding and differential compounding respectively.

Alternating-Current Machines

(a) Polyphase, Asynchronous, or Induction Motors.—In motors of this class the speed is constant except for a slight drop due to slip, amounting to not more than 5 per cent. at full load, and depends solely on the frequency of the supply and the number of poles for which the motor is wound.

The torque varies as the current taken from the line, and both are proportional to the square of the applied voltage. It is important to bear this in mind, for if the voltage only drops as much as 10 per cent., the torque will drop as much as 19 per cent., perhaps sufficient in the case of a heavy load to throw the machine out of step and bring it to a standstill.

Curves of torque, speed, and B.H.P. for a typical motor of this class are given in Fig. 5.

In order to deal with its starting characteristics, it will be necessary to subdivide this class of motor as follows:

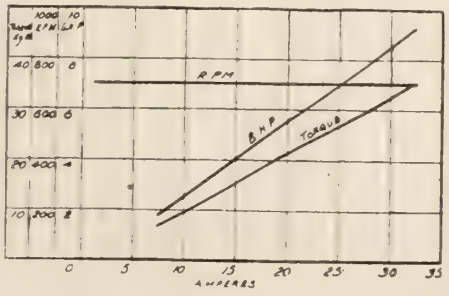
1. Squirrel-cage Type.—These motors may be started in the following ways: First, small motors may be switched direct on to the mains, and will then give a starting torque of about double full-load torque with about six times the normal full-load current. This method of starting is naturally not advisable except in the case of very small machines starting light.

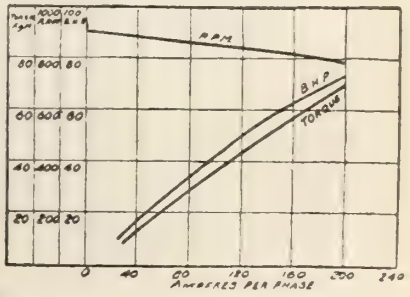
Secondly, by means of stator rheostatic starters. The effect of inserting resistance in the stator is to reduce the voltage across the stator windings, and limit the starting current; but this, unfortunately, results in reducing the torque to a much greater extent—namely, as the square of the voltage, as explained above. If sufficient resistance is inserted to limit the current to even as high a value as two and a half times full-load current, yet the motor will develop only 10 to 25 per cent. of full-load torque; a loose pulley or clutch is therefore necessary for starting in such cases.

Thirdly, by means of star-delta switching in the case of three-phase and series-parallel switching in the case of two-phase motors: If a three-phase motor is started in this way the voltage across each phase winding at starting is reduced to about 0.6 time the running voltage. Consequently the starting current taken will be about 0.36 of the direct-connected starting current, or about two and a half times the normal full-load current. At the same time, the starting torque will be reduced to about 0.36 of full-load torque.

Fourthly, by means of an auto-transformer starter or compensator. The effect of using this type of starter is exactly similar to that obtaining with star-delta starting. Thus the direct-connected starting current and the starting torque are reduced approximately as the square of the reduction in the starting voltage. The voltage tappings very usually employed are 0.5, 0.6, and 0.75 of the line voltage, corresponding to motor starting currents of 1.5, 2.5, and 3.5 times full-load current, and starting torques of about 0.25, 0.36, and 0.56 of full-load torque. The corresponding line currents will be approximately ¾, 1½, and 2½ times full-load current.

2. Slip-ring Type.—Wound-rotor machines are started by inserting resistance in the rotor circuit to limit the starting current to any desired value. When started in this way full-load torque will be obtained with one to one and a quarter time normal full-load current. The relation between torque and current for





other values of the latter is roughly as follows:

[illegible] of full-load current gives 25 % of torque.
[illegible] of full-load current gives 33 1-3% of torque.
65% of full-load current gives 50 % of torque.
70% of full-load current gives 66 2-3% of torque.
80% of full-load current gives 75 % of torque.

It will therefore be seen that, if a starting torque of 25 per cent. or more of full-load torque with not more than full-load current is required, a slip-ring machine is essential.

3. Self-starting Type.—There is another class of polyphase induction motor having all the advantages of a squirrel-cage machine, but which will start up satisfactorily with a high starting torque without the use of any auxiliary starting apparatus. In motors of this type the rotor winding is composed of two or more sections, which are normally connected so as to give a high resistance at starting, the connection being automatically changed to give a low resistance when the motor has reached 70 to 80 per cent. of its normal speed, by means of a switch operated by a centrifugal governor.

In one motor of this class, one-third of the rotor copper is in circuit at starting, the remaining two-thirds being open-circuited and connected to a short-circuiting device, which operates when a predetermined speed has been reached.

In another motor of this class the rotor winding is in two or three sections, which are connected in series for starting and in parallel by means of the governor switch when up to 70 to 80 per cent. of the normal speed.

Motors of this class are normally designed to give at starting about 2½ times full-load torque with two to three times full-load current, depending on the size, make, etc. Compare this with the starting torque of about 70 per cent. of full-load torque for three times full-load line current of a squirrel cage motor auto-transformer starter.

If desired, the starting current taken by these motors can be reduced by means of any of the starters employed with squirrel-cage motors, but, of course, with a corresponding reduction in starting torque.

As these motors run as ordinary induction motors, the running characteristics are exactly similar to the latter class of machine.

(b) Single-phase Motors.—1 Induction Type.—As in the case of polyphase induction motors, the speed of these machines depends merely on the frequency of the supply and the number of poles for which the machine is wound, whilst the torque is approximately taken, that is to the load. The characterization curve is similar to those of polyphase machines. Owing to the fact that the field produced by a single-phase current is oscillating and not revolving, as in the case of two or three-phase, a single-phase motor has no inherent starting torque, the latter only being produced when the rotor revolves; consequently an auxiliary or starting phase with a phase-splitting device (consisting usually of a non-inductive resistance in the main winding and a choking coil in the auxiliary winding) has to be provided. Even then the starting torque is but feeble, and a loose pulley must always be employed.

These machines are built of the squirrel-cage and slip-ring types. A squirrel-cage machine will not give more than 10 to 15 per cent. of full-load current. The starting qualities of the slip-ring type are rather better, but even in this case a starting torque of not more than 20 per cent. of full-load torque will be obtained with 100 to 125 per cent. of full-load current.

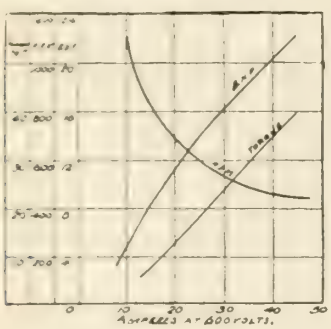


FIG. 1.

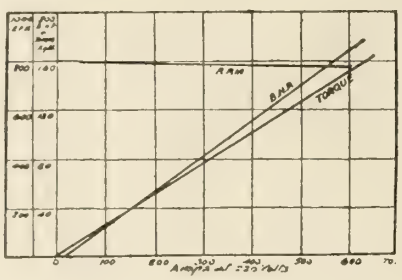

FIG. 2.

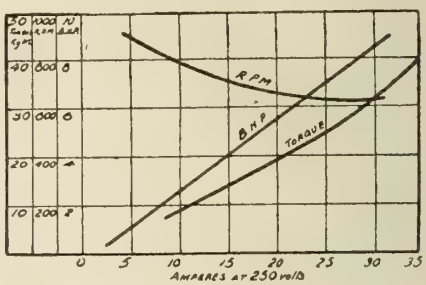

FIG. 3.

2. Repulsion Induction Type.—These machines are really repulsion motors as far as construction is concerned, and start as such, but are fitted with a centrifugal governor which short-circuits the commutator and lifts the brushes when the motor has got up to speed, so that it continues to run as an ordinary single-phase induction motor. The running characteristics are therefore exactly similar to the latter type, but as against the very feeble starting torque of the split-phase motor they have a starting torque of about 2½ times full-load torque with about 2½ times normal full-load current.

If it is necessary to limit the initial current taken from the mains to a lower value, a plain series starting resistance, such as is used with a direct-current motor, is employed. This tends to raise the power factor so that full load current at starting will give about 1 to 1½ times full-load torque.

ELECTRICALLY DRIVEN PUMPS.

At a meeting of the Institution of Water Engineers, held at Birmingham, Mr. C. F. Bekenn, A.M.Inst.C.E., contributed a paper on "The Application of Turbine-pumps to Water Supply." In the course of the paper the author remarked that while turbine-pumps could be driven by any type of prime mover, he placed the electric motor in the first place as regarded efficiency and convenience. The installation costs, including foundations, were low, and the space occupied was small. The pump and motor required very little attention, as the bearings were automatically lubricated with oil-rings. Low installation costs permitted the sets to be conveniently distributed. They were easily started up, and could also be operated from a distance or automatically stopped and started, either by varying levels in the reservoir or by varying pressures between pre-determined limits. The alternating-current motor was preferable to the direct-current machine owing to the absence of a commutator, and most of the installations at work were driven by A.C. motors. If a heavy current rush on starting was permissible, it was advisable to install squirrel-cage motors, as the turbine-pump, owing to its low-starting torque, could easily be started up by this type of motor. One point that had to be noted was that the slip between synchronous and asynchronous speeds could not be exactly determined, and might vary as much as 2 to 4%. The B.H.P. required to drive the turbine-pump varied as the cube of the speed, so that should the slip be less by, say, 2% than the makers' original estimate, the B.H.P. would be considerably increased, with a proportionate increase of water. For squirrel-cage motors, auto-transformer starters of the oil-immersed type should be installed, with no-volt and overload release on the three circuits, these operating in the stator circuit. The starter consisted of a transformer with tappings on the windings, of varying percentages of the line voltage. The tappings should be selected as best suitable for the starting torque, and as that was not more than 50% of full load torque, a low percentage, say, 25 or 30%, was sufficient. The automatic features were arranged in the "running" position only, because in the "starting" position they would at once break the circuit owing to the rush of current, which was generally two or three times the ordinary running current. This type of starter required only three terminals on the motor and six on the starter—namely, three for the motor and three for the line. In cases where low starting currents were necessary, slip-ring

motors should be installed, as those would start up with 50 per cent. of full load torque using normal running current. With reference to motor terminals, trifurcating boxes were recommended as providing an extremely neat finish and effectively enclosing all the live parts. In large pumping-stations, where the current had to be carried some distance and the motor-power was at least 150B.H.P., the motors could be wound for 6,000 volts, and so dispense with transformers. For motors of less than 150B.H.P. a lower voltage was necessary on account of the difficulties of insulation in the coil windings.

Proceeding to discuss the relative costs of steam and electric pumps, the author gave several examples as showing that economy was on the side of the latter. Thus, the City of Hereford had three electrically driven pumps working off a three-phase, 50-cycle circuit, two sets delivering 60,000 gals. per hour, and the other set delivering 20,000 gals. per hour, against a total lift of 120 ft. in each case. The costs, as recently determined, showed that with electricity at 0.75d. per unit, the cost of electric pumping was 0.5d., as compared with 0.426d. per 100,000 gals., the cost of steam pumping. Those figures included men's wages, lubricating oil, waste, etc. The Newbury District Water Company, early in the year 1912, made careful tests of its compound condensing steam pumps, and of its electric pumps. The latter were driven by direct-current motors, one set having a capacity of 30,000 gals. per hour against 185 ft. lift, one set 20,000 gals. per hour against 150 ft. lift, and a further set 3,000 gals. per hour against 164 ft. The 1912 costs worked out at 1.18d. per 100,000 ft.-gals. for steam, as against 0.957d. for electrically driven pumps, but for 1920 the figures are 2.61d. and 1.576d. respectively. The Chester Waterworks Co. had installed a Diesel engine and dynamo supplying power to drive turbine pumps built by Sulzer and the Rees Roturbo Company, at two separate stations connected by cable. The costs, including all transmission losses and "shut-downs" due to interruption in working consequent on erection of additional plant, came to 0.657d. per 1,000 gals. 100 ft.

Advantages of Flat Furnace Arches

THE recent development of flat arches to a point of distinctive serviceability for boiler furnace construction lies in many cases in simplified design and besides offers greater convenience in the matter of routine repairs. Frequently the design of furnaces calls for reflecting surfaces at various angles and in some special cases some advantages are to be gained in using curved surfaces. The use of sprung arches limits the latitude of construction in these respects and thus many possibilities for furnace improvement go begging.

Also in natural draft furnaces wherein the construction is more or less standard, the support of the necessary curtain wall requires the construction of a separate sprung arch for this purpose although this arch has no function in the combustion of the fuel itself. In designs calling for step-up arches the construction is further complicated. On the other hand flat suspended arches have answered to a considerable extent the criticisms of the usual construction in two respects in particular; viz.: (1) the design eliminates a quite usual source of air leakage into the furnace through the clearance space between arches, and (2) the gaining of increased available headroom which, in the case of forced blast stokers is particularly desirable. In other minor respects flat arches have overcome the effect of sag in sprung arches, in which case no real effective seal can be made either be the "keying up" with the curtain wall arch, or between the curtain wall and roof, as is the case on B. & W. or similar type boilers.

In the matter of routine repairs of sprung arches, the rebuilding of a bock ring at the fire end requires that the new brick be bonded with the old, and this is rather a difficult matter to do without subsequent cracking. Besides the "keying up" with the curtain wall support arch in place is by no means an easy matter. Here again the flat suspended arch offers convenience of repairs with an increased amount of salvage of the used materials.

As to the proper position, length and pitch of fire arches, it can be stated that there is no exact or precise method of determination, thus giving rise to much diversity of opinion as to these matters among engineers. The only reliable guide is trial and experiments; there are, however, many fundamental principles from a combustion standpoint which determine these factors with some practical degree of accuracy, but too frequently the overall design of boiler and furnace is such that the best proportioning is interfered with, particularly in the matter of the position of the grate with respect to the boiler. In standard construction the art has developed certain relations, which, from the results of actual test and practice appear to offer the most economical results. It is proposed to consider a few of these in this instance.

The function of an ignition arch is to produce as intense a heat reflection at the point of ignition as is possible. The temperatures obtained at this point are, of course, largely dependent upon the sizing and general character of the coal, but most of all to the air supply over this area. In the case of natural draft the temperature possibilities are limited mostly on account of the latter reason, while in forced draft stokers the problem of ignition is simple and controllable. On natural draft a number of trials have shown that the most effective distance between the ignition arch and the fuel bed is from 6 in. to 7 in. and that there is no particular advantage in extending the length of this surface beyond 12 inches insofar as benefiting combustion is concerned. There are, however, many instances where mechanical difficulties have necessitated a departure from this practice. Under forced draft conditions the larger volume of gases requires a greater space between the fuel bed and ignition arch, it being approximately proportional to the amount of increased fuel burned per square foot, per hour. The figures given above apply to a coal rate of 40 lbs. free burning coal per square foot per hour and an 8 in. fuel bed.

The height of the main or fire arch should be such that the intensity of the heat reflection is sufficient to insure continuous combustion the full length of the grate, and in addition provide sufficient volume for the intimate mixture and easy flow of gases of combustion. It is thus evident that the height above the fuel bed is a function of the coal rate per square foot per hour. Under normal natural draft coal rate of 40 lbs. the most effective point is shown by experiment to be between 13 and 20 inches at the front end. However, an arch constructed in accordance with this minimum require that the pitch be such that the increasing sectional area be proportional to the increasing flue gas volume. This steep pitch does not permit of an intimate mixture of gases, particularly over the area of destructive distillation, and unburned hydro-carbons and smoke are the result. These objectionable conditions are removed by raising the front end to the maximum height and using only a slight pitch of about 1 in. per foot. Under forced blast conditions additional furnace volume is required not only on account of the increased coal rate of 60 lbs., excellent conditions were obtained with the main arch 4 ft. above the grate.

Theoretically, the arch projection which gives 100 per cent. over the grate should be correct, but a practical design on this basis is obviously impossible. Good practice calls for a 65 per cent. projection, which gives the maximum length possible, while at the same time providing sufficient exit area from the furnace. Except for this limiting factor and easy flow of air through the fuel bed at the ignition arch, the longer the arch the lower the carbon content of the ash. The disposition to smoke is also accordingly reduced. In the case of forced blast stokers where ample furnace volume is provided, arches of this length are not required as far as combustion of fuel on the grate is concerned.

In general, it can be said that in furnace design the type of boiler and its position with respect to the grate in many cases required deviation from the

(Continued on page 385)

A Course of Instruction for the Graded Certificate

We Will in This Course Go Through the Mathematical and Theoretical Work to Cover Every Grade of Certificate Issued by the Ontario Board

By T. H. FENNER

IN our last article we arrived at the leading dimensions of a boiler to give 100 h.p. at the standard rating of 34½ lb. water from and at 212 deg. per horse power. These we found to be 72 in. in diameter by 18 ft. long. As the pressure determined on was to be 125 lbs. per square inch we must decide on the thickness of shell and type of riveted joints on the longitudinal seam to carry this pressure, with due allowance for the factor of safety. This factor of safety must be determined by the rules given in the Ontario Government Act, and will vary according to the conditions under which the boiler is built. Following are the rules as given in the handbook issued by the Government.

Factors of Safety

Boilers well designed, well constructed, and made of good material, should be allowed a higher working pressure than boilers inferior in any of the above respects, and unless this is done the superior boiler is placed at a disadvantage and the use of good workmanship and material will be discouraged. To provide for the above, the following rules regarding factors of safety for cylindrical boilers and cylindrical parts of boilers have been adopted.

When cylindrical shells of boilers are made of the best material either in iron or steel with all holes drilled in place from the solid plate, the plates afterwards taken apart and the burrs removed, and all longitudinal seams fitted with double butt straps, each at least ⅝ the thickness of the plates they cover, the seams being double riveted with rivets having an allowance of not more than 75 per cent. over the single shear, and having the circumferential seams constructed so that the per cent. is at least one half that of the longitudinal seam and provided that the boiler has been inspected by inspectors authorized by the act during the whole period of construction in accordance with these regulations, then 4.5 may be used as a factor of safety, but when the above conditions have not been complied with the additions to the following scale must be added to the factor of safety according to the circumstances of each case.

To be added to the factor of 4.5.

A .10 Holes in longitudinal seams, fair and good, but drilled from solid out of place after bending edges of plates.

B .20 Holes in longitudinal seam, fair and good, drilled from solid out of place before bending edges of plate.

C .20 Holes in longitudinal seams, fair and good, punched after bending edges of plates and reamed after assembling.

D .30 Holes in longitudinal seams, fair and good, punched before bending edges of plates and reamed after assembling.

E .07 Holes in circumferential seams, fair and good, drilled from solid out of place after rolling plates.

F .10. Holes in circumferential seams, fair and good, drilled from solid out of place before rolling plates.

G .10 Holes in circumferential seams, fair and good, punched after rolling plates and reamed after assembling.

H .15 Holes in circumferential seams, fair and good, punched before rolling plates and reamed after assembling.

I .70 Longitudinal seams, if double butt straps are not fitted and the said seams are lapped and double riveted.

J .50 Longitudinal seams, if double butt straps are not fitted and the said seams are lap and treble riveted.

K .60 Longitudinal seams, if only single butt straps are fitted and the said seams are double riveted.

L 1.00 Longitudinal seams, when any description of joint is only single riveted or when double straps are used and only one row of rivets in double shear.

M .50 Holes or rivets in longitudinal seams if not fair and not good.

N .20 Holes or rivets in circumferential seams not fair or not good.

O .40 Holes in any seams not properly spaced in crossing.

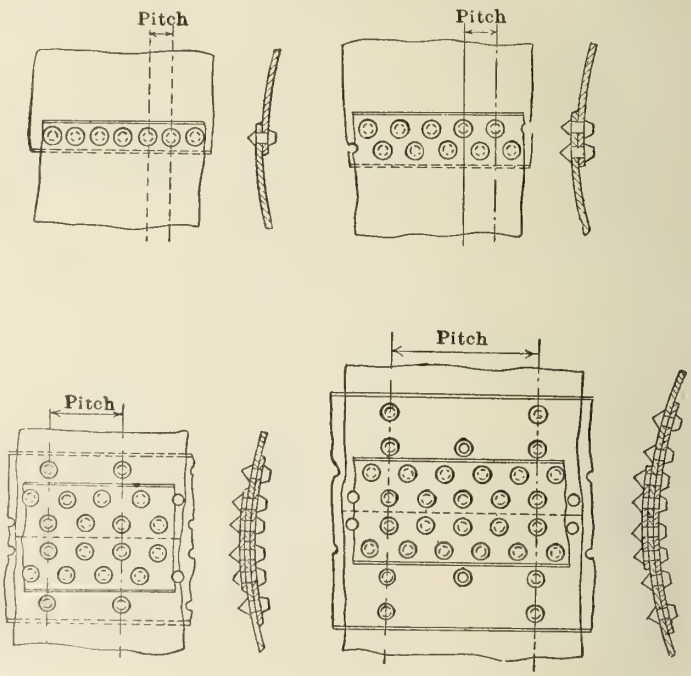
P .40 When material is doubtful and not properly certified in accordance with regulations.

Q .50 If joints are not close fitting the plate being open when boiler is finished or workmanship unsatisfactory.

R .50 If boiler has not been inspected by inspectors authorized by the act during the whole period of construction in accordance with these regulations.

The inspector is allowed some latitude according to his judgment of the circumstances in appying these regulations.

In designing a boiler, the highest factor of safety will be aimed at. This means that the best possible type of joint must be used on the longitudinal seam and that workmanship and material must be good. Before going any further we will therefore discuss the different types of joints.



TYPES OF RIVETED JOINTS

Kinds of Joints

The efficiency of a riveted joint is expressed always as a percentage of the strength of a solid plate. When holes are drilled or punched out of a plate to allow of riveting, the plate is weakened by the amount of metal cut out. If we have a plate of one square inch section, and remove .25 square inches in drilling, the section remaining is only .75, and the resistance of the plate to stress will be only 75 per cent. of its original resistance. This would represent what is known as per cent. of plate strength to solid plate. This is only one factor. The second factor is the proportion that the strength of

the rivets bears to the strength of the solid plate. This will depend on the diameter and number of rivets in the unit section of plate considered, and is also expressed as a percentage. We shall consider the means of arriving at these efficiencies shortly.

There are several styles of riveted joints, and two distinct classes. The lap type of joint is so called because it is made by lapping the edges of the plate over each other and riveting them together. The second type is known as a butt joint and is made by bringing together the edges of the plates to be joined and placing a broad plate over them, riveting all three plates together. In many cases two cover plates are used. These two types of joints are subject to various modifications. Thus a lap joint may be single, double, or treble riveted and the rivets may be placed in regular rows or in staggered rows, known as chain or zig-zag riveting. The butt strap joint may be made with one or two straps, with equal or unequal straps, with double, treble or quadruple riveting. The type of joint selected will depend upon the pressure to be carried, cost of manufacture and rules of the province in which the boiler is to work. The cut here shown illustrates the type of joints mentioned above.

To Find Efficiency of Joint

The efficiency of a riveted joint varies with the diameter of rivets, pitch of rivets, number of rivets in a pitch, and the thickness of the plate. In considering riveted joint efficiency, the unit of plate area considered is always contained within a pitch or between the centre lines of two adjacent rivets. Where there is more than one row of rivets the pitch of the rivets in the outer row is taken. We will explain each type as we come to them. The most simple is of course the single riveted lap joint. Suppose we have a plate of 5-16 inch in thickness, and with ⅝ rivets pitch 2 inches. We have to consider the strength of the joint as compared to the solid plate. We will consider the plate to be of 60,000 lbs. tensile strength. We shall therefore have a section, before any drilling is done, of 2 x 5-16 = ⅝ square inches. This section will have a resistance of 60,000 x ⅝ = 37,500 lbs. Now, after drilling, the amount of metal removed will be in diameter just equal to the diameter of one rivet because in the section we are considering there will be just half a hole on each side. A glance at the sketch which shows the pitch of line passing through the centre of rivets will make this clear. Therefore the amount of metal removed will be equal to the diameter of one rivet multiplied by the thickness of the plate, or

$\frac{5}{8} \times \frac{5}{16} = \frac{25}{128}$. This amount subtracted from the original area will give the section remaining, and if this remainder be divided by the original section we will have a fraction, representing the proportion of original section remaining. To express this as a percentage we multiply by 100. Now to follow out the procedure step by step.

Let

P = pitch.
d = diameter of rivet.
t = thickness of plate.

We have a plate section of pitch P, and thickness t, the area being Pt. The rivet area will be equal to dt, so that when the holes are drilled we shall have

$$Pt - dt = P - d$$

the t on each side cancelling out.

The proportion of plate section remaining is $\frac{P-d}{P}$ and the percentage of plate to solid plate is $\frac{P-d}{P} \times 100$. Substituting figures, we get

$$Pt = 2 \times \frac{5}{16}$$

$$dt = \frac{5}{8} \times \frac{5}{16}$$

$$Pt - dt = 2 \times \frac{5}{16} - \frac{5}{8} \times \frac{5}{16}$$

$$P - d = 2 - \frac{5}{8}$$

$$\frac{P - d}{P} = \frac{2 - \frac{5}{8}}{2}$$

$$\frac{P - d}{P} \times 100 = \frac{2 - \frac{5}{8}}{2} \times 100$$

$$= \frac{2 - .625}{2} \times 100$$

$$= \frac{1.375}{2} \times 100$$

$$= 68.75$$

So that the proportion of plate strength to solid plate is 68.75 per cent.

This formu'a is always used, and may be set down

$\frac{P - D}{P} \times 100 =$ per cent. of plate strength to solid plate.

In the Ontario regulations the plate efficiency is symbolized by the letters Kt, so the formula is

$$\frac{P - D}{P} \times 100 \text{ Kt}$$

The next point to consider is the efficiency of the rivets in the joint. This is the proportion that the area of the rivet in the pitch limit bears to the unit section of plate. As rivets are not as strong in resisting shearing stresses as they are in resisting tensile stresses, an allowance must be made for this difference. The Ontario regulations use the constant C, and this is expressed

$$C = \frac{\text{Shearing strength of rivets}}{\text{Tensile strength of plate}}$$

C may be taken as

.85 for iron rivets in iron plates
.70 for steel rivets in steel plates.
.65 for iron rivets in steel plates.

In the joint we are considering there is but one rivet in the pitch, and as there are but two plates which the rivets pass through they are in single shear. We will then have an area of d x d x .7854, divided by the area of the unit section, which is P x t. This is expressed in the formula:

$\frac{a \times n}{P \times t} \times C \times 100 =$ per cent. of rivets' strength to solid plate.

So we have

$$\frac{5 \times 5 \times .7854 \times 1 \times 16 \times C}{8 \times 8 \times 2 \times 5} \times 100 = \text{Ks}$$

This worked out becomes, if we take C as .85

$$\frac{5 \times .7854 \times 85}{8} = 41.72 \text{ per cent.}$$

If we neglected the constant C we would get about 49 per cent. This lowest percentage is the one used in calculating the working pressure of the boiler. In our next article we will consider the strength of riveted joints of more complicated design.

ADVANTAGES OF FLAT ARCHES

(Continued from page 283)

principles of good practice. With boilers of the B. & W. type or Heine type where sufficient headroom obtains, the opportunities for flexible design are not interfered with, but in the case of Stirling, Conolly and similar types, practical conditions have to be overcome, and in many cases at the expense of efficiency. It is obviously quite difficult to formulate a code of furnace practice to cover all special conditions, but on the other hand those principles established by usage and corroborated by experiment should offer the furnace designer considerable insurance against failure.

Many engineers are at the present time prone to accept the fantastic and gamble with untried principles. Again there are others who opine that the mere changing of a detail is a cure for all ills. The best guide after all that can be said, is trial and experiment.

A. S. M. E. MEETING

The 1920 annual meeting of the American Society of Mechanical Engineers will be held in the Engineering Societies Building, 29 West 39th Street, New York City, from December 7 to December 10.

Sessions will be held on the subjects of appraisal and valuation, and the application of engineering to woodworking.

The newly founded profession sections on management, power, fuels, machine shop, railroads and textiles will also conduct sessions to consider the vital problems in their field. In addition a number of valuable papers will be presented at general sessions.

A memorial session for Dr. Brashear is planned, as a fitting tribute to his life and work.

The Open Type Locomotive Feed Water Heater

The Theory and Practice of Feed Water Heating by This Type of Heater is Discussed by the Author in a Paper Read Before the A.S.M.E.

By THOMAS C. McBRIDE

THE use of feedwater heaters on locomotives dates back to the beginning of the locomotive itself. There are records of the application of an "open" or "injection" type heater to a locomotive in England in 1827, and an English patent of 1828 describes a tubular heater for the same purpose. Ross Winans of Baltimore applied tubular heaters to two types of Baltimore & Ohio railroad locomotives in 1836. It is worthy of note that the desirability of the feedwater heater for the locomotive was recognized at these early dates, although it must be appreciated that the advantages possible at that time were proportionately greater than at the present time because of the low steam pressure then in use.

There is much of interest in the history of locomotive feedwater heating in a paper, Feedwater Heaters and Their Development by J. Snowden Bell which was presented at the fiftieth annual meeting of the American Railway Master Mechanics Association, in June, 1918. Every conceivable type of heater and all possible sources of heat, even the hot ashes, seem to have been proposed or tried, and in view of the amount of study that has been given to the subject it seems rather remarkable that locomotive feedwater heating is not now in more general use. Possibly the reason lies in the fact that it is only in comparatively recent years that the essentials of heater performance and pump operation have been understood. Furthermore the small size of the locomotives formerly in general use limited the saving per locomotive, and the general adoption of the injector, because of its simplicity and convenience, rendered feedwater heating impossible, for injectors heat the water which they use to such an extent by live steam that there is little or no opportunity for further heating.

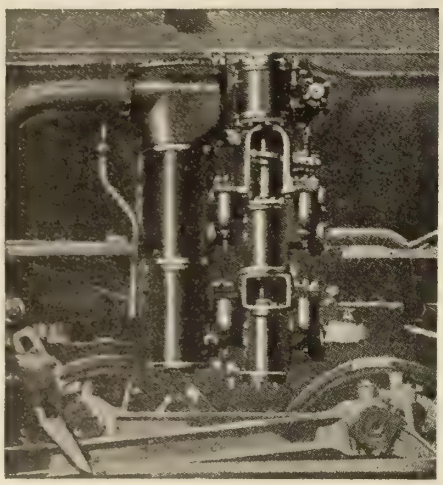


FIG. 1—PUMP AND HEATER APPLIED TO MIKADO LOCOMOTIVE.

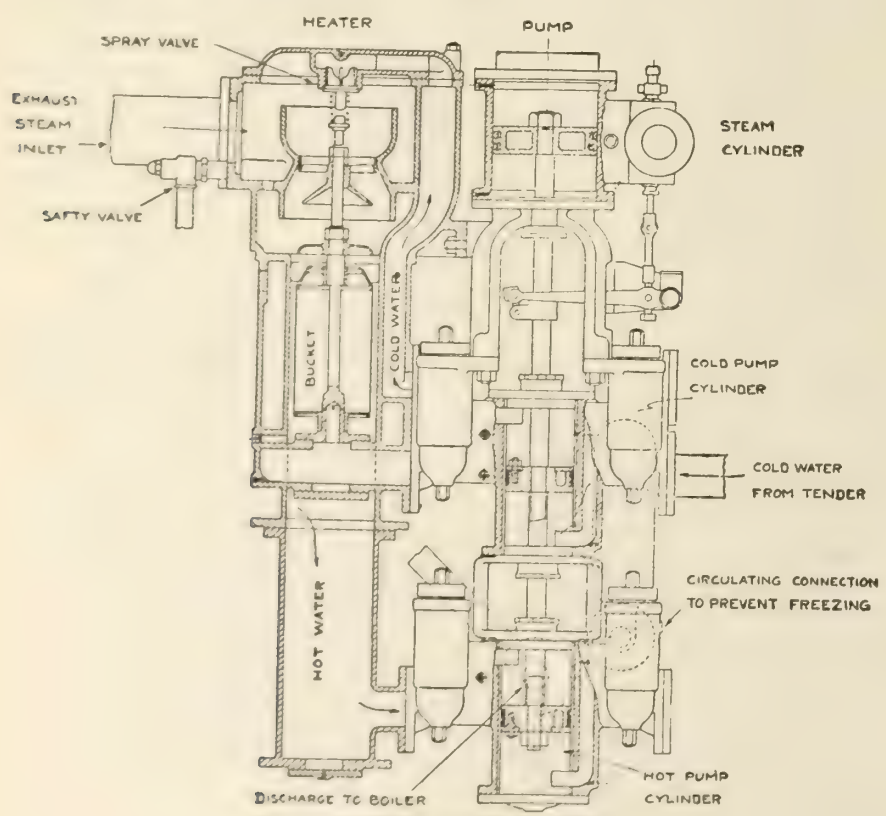

FIG. 2—SECTION OF THE HEATER.

There are two possible sources in a locomotive from which otherwise waste heat may be obtained to heat the feedwater: (a) the waste gases in the smokebox or stack, (b) the exhaust steam. Stationary practice with economizers indicates the waste-gas heaters cannot be supplied with cold water because the accumulation of condensation and soot on them seriously interferes with their efficiency. It is, therefore, necessary to turn to the exhaust steam for the source of heat and to develop this type of heater first, leaving the waste-gas heater for later development as may be found either necessary or advisable.

The exhaust steam heater may be either of the open or injection type in which the exhaust steam comes into direct contact with the cold feedwater so that the water condensed from this exhaust steam is added to and mixed with this feedwater; or, of the closed or surface type in which the heat from the condensation of the exhaust steam passes to the feedwater through thin sheets of metal, generally in the form of thin brass tubes. Practically all of the development work to date that has been at all successful has considered only the surface type. There are a great many heaters of this type in service in Europe, but there are objections to it for locomotive use. It is a complex and delicate structure; it also wastes the water condensed from the exhaust steam with its heat or raises complications as to saving it, and it requires enough exhaust steam to heat all of the feedwater. On the other hand, the open or injection type of heater necessarily recovers both the water condensed from the exhaust steam and its heat so that both are returned direct to the boiler with the water taken from the tender. Less water is therefore taken from the tender and less exhaust steam is required for the heating.

Description of a New Type of Heater

With these thoughts in mind, the author has devised a system of locomotive feedwater heating which makes use of a heater of the open type which is manufactured and marketed by the Worthington Pump and Machinery Corporation. The system follows marine practice in heaters of this type, and the pump and heater have been combined into a single unit which can be conveniently attached to the side of the locomotive

boiler as is the practice with air-brake compressors. Fig. 1 shows a unit with a capacity of 60,000 lb. of feedwater per hour in service on a Mikado locomotive. Fig. 2 is a sectional view of the heater and pump. In these illustrations the heater is shown at the left, the feed pump at the right.

The heater is a simple cast-iron box, the upper part of which is supplied with exhaust steam taken from the locomotive through holes cut in the back of the cylinder saddle and a pipe which has in it a stop check valve and an oil separator, the latter having a small hole in it so that there is a continuous drip for the oil.

The pump is of the vertical type attached to the side of the heater by the various pipe connections. The steam cylinder of the pump is at the top, and it has two water cylinders clearly shown in the illustrations, both operated from the same piston rod. The water cylinder in the middle of the pump takes cold water from the tender and delivers it through a port in the side of the heater to a spray valve in the extreme top of the heater where it is sprayed into the exhaust steam that fills the top of the heater. This condenses as much of the exhaust steam as the water needs to heat it, and the mixture, dropping to the bottom of the heater is taken by the other pump cylinder and delivered to the boiler through the usual check valve. The pump cylinder which takes the cold water from the tender and delivers it to the heater is really a measuring device which feeds into the heat approximately the same amount of water that the lower pump cylinder takes out of the heater, but the varying amounts of exhaust steam condensed in heating the feedwater cause a tendency for a slight excess of water to accumulate so that in time the heater would become flooded. This is prevented by returning this excess water under the control of a bucket in the heater to the pump cylinder in the middle of the pump through one of its pump-suction valves serving this water alone.

The pump is driven by saturated steam taken from the locomotive boiler through a 1-in. steam pipe and controlled by a throttle valve in the cab within convenient reach of the engineer. The exhaust steam from the pump is led into the back of the stop check valve where it mixes with the exhaust steam from the locomotive, and passes with it through the oil separator to the heater. These pipe connections as well as the cold-water pipe from the tender passing back of the air-brake compressor and the feed line from the lower pump cylinder to the boiler are shown in Fig. 1.

The adoption of the open heater for the locomotive may seem a radical step, but from this description it will be evident that no new elements are used. The heater itself is of a general type that has been in use in marine service for at least twenty years. The open heater with the oil separator to remove the oil from the exhaust steam before it enters the heater because of its merits has been almost universally adopted for stationary plants. One of these heater and pump units was thoroughy tested out on the locomotive test plant of the Pennsylvania Railroad at Altoona, Pa., in 1917, and has been in operation on road service since October 1918. Three more units have been in operation for approximately a year on pooled locomotives and have given no trouble other than the usual pump maintenance. Nothing has developed indicating that the open heater as a type is not well adapted to the locomotive and the coal and water savings have been so marked as to be evident to the crew.

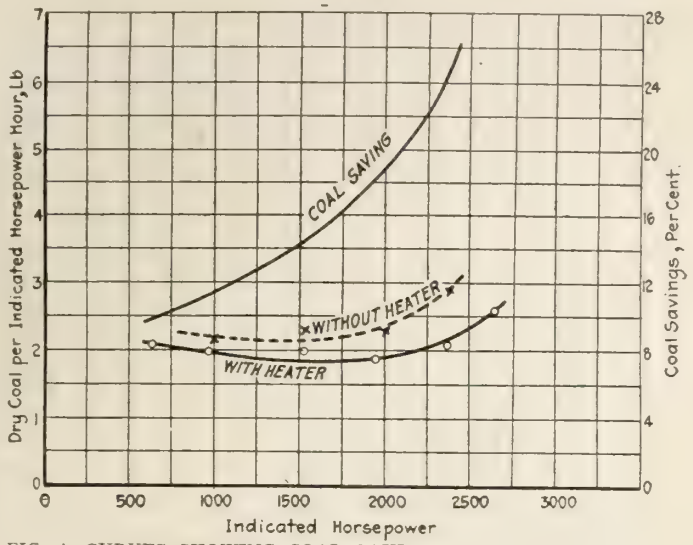

FIG. 4—CURVES SHOWING COAL SAVING BASED ON INDICATED HORSEPOWER.

The pump is much easier to operate than an injector as it requires only a slight turn of the 1-in. throttle valve to either start it or to make it run faster or slower as the boiler may need more or less water. It does not require priming and can be operated continuously at low capacities where the injector must be stopped and started periodically.

The feed pump should not be used, as is often done with the injector, to fill the boiler on the down grade and then be shut off as long as possible on the up grade; first, because there is not as much inducement or necessity for operating it in this way, and secondly, because the prime purpose of the heater is to recover heat and it can only do so when the locomotive is pulling and exhaust steam is available for the heating. If the injector is operated continuously and maintains a constant water level in the boiler each pound of steam generated will require 1276 B. t.u. from the fire with 200 lb. steam pressure, 150 deg. superheat, and 40 deg. water in the tender. If the injector is shut off each pound of steam will require somewhat more than 925 B.t u.

so that the amount of steam from the same fire will be increased less than 38 per cent. It will later be shown that under the same conditions the feedwater heater would increase the amount of steam about 13.6 per cent. The feedwater heater will, therefore, materially increase the amount of steam on the up grade, although not to the extent possible in the case of the injector and should be depended upon to feed the boiler entirely on the up grade with the consequent greater amount of heat recovered from the exhaust and more nearly constant water level in the boiler.

Advantages of Locomotive Feedwater Heating

It is not possible to make an exact general statement of the advantages to be obtained from locomotive feedwater heating, because much depends on the particular locomotive to which the heater is to be attached, the capacity at which it is worked, the temperature of the water in the tender, and the basis on which the advantages obtained are stated.

We are able to base our notions as to the advantages of feedwater heating on the results obtained in stationary practice where the coal saving is very properly considered as equivalent to the reduction in the amount of heat necessary to evaporate the water because of the higher temperature at which the water is delivered to the boiler. In the case of the locomotive, however, with its very complicated relations of the different operations that are going on, and the very wide range of capacity through which the boiler is operated, there is generally a much greater coal saving than in stationary practice. Three factors enter into the final result. These are as follows:

1. The reduction in the amount of heat required to evaporate the water in the boiler, which might be called the *heat saving due to the feedwater heater.*

2. The reduction in the amount of heat required results in a greater reduction in the amount of coal required because of the better efficiency of the boiler at the lower rate of combustion. These two factors give the *coal saving based on water evaporated.*

3. The exhaust steam taken by the heater from the exhaust ports of the locomotive reduces slightly the back pressure in the locomotive and should show some advantage. All three factors combined will give *the coal saving based on indicated horsepower.*

An analysis of these three factors will show the coal and water saving referred to the steam that is used in the locomotive cylinders, and therefore, the minimum saving since it does not include the saving in generating the steam used by the auxiliaries. It is necessary to make this analysis partly theoretical assuming certain constant operating conditions in order that a fair comparison may be made of the effect of the heater on different locomotives and at different locomotive capacities. It can only apply to the coal burned while running since the heater can have no influence while standing or at terminals. The percentage of coal saving due to the heater, and to a lesser extent the percentage of water saving when based on ton miles, the month, or the year will be less than the percentage while running by an amount determined by the use made of the locomotives.

Heat Saving Due to Feedwater Heater

The first factor, the heat saving, is determined by the amount the feedwater is heated by exhaust steam taken from the locomotive. This factor will evidently be greatest when the tender-water temperature is low and when the exhaust steam pressure in the heater is highest, as this pressure determines the temperature to which the feedwater can be heated. This pressure will be highest when the locomotive is working hard, and when the exhaust steam for the heater is taken from that part of the steam valve chests or cylinder saddles where its pressure is greatest.

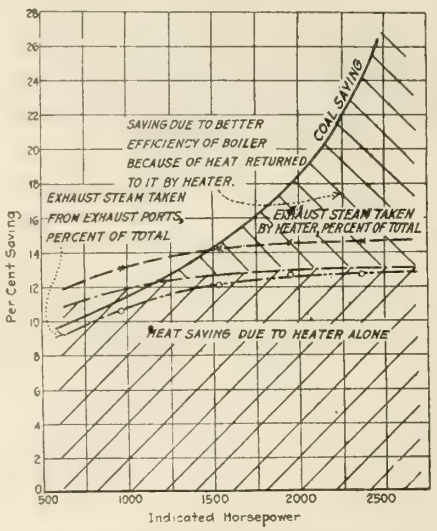

FIG. 5—ANALYSIS OF COAL SAVING BASED ON I.H.P. WITH EXHAUST STEAM LIFT AVAILABLE FOR DRAFT.

The exhaust steam from the feed pump need not be be wasted, since it can be and is used in the feedwater heater, but this use prevents the recovery of the same amount of exhaust steam and heat from the exhaust of the locomotive. The amount of steam used by the feed pump is, therefore, a direct charge against the saving due to feedwater heating as compared to injector operation when considered in the light of recovery of waste heat from the locomotive exhaust, or when estimated by the temperature rise of the feedwater in the heater.

Test plant results and actual daily operation on the road with superheated steam locomotives show that the feedwater heater described can be depended on to effect a reduction of at least 10 per cent. in the summer time and 12 per cent. in the winter time in the amount of heat required to evaporate the water and superheat the steam. This heat saving will not be constant at these figures but will vary with the capacity at which the locomotive is worked because the steam pressure in the heater determines the temperature to which the feedwater can be heated. These figures can, however, be conservatively accepted as representing average working conditions at which the greater part of the coal is burned.

The tabulation given in Table 1 is based on heating the feedwater to 215 deg. This is quite conservative as it has been found easily possible to obtain this temperature with this heater even with tender-water temperatures of 40 deg. and on locomotives worked at less than two-thirds of their maximum capacity. The tabulation shows that greater heat saving is possible with saturated than with superheated steam locomotives; therefore the percentage of coal saving will be greater with saturated than with superheated steam locomotives. Table 2 gives the exhaust steam required for the heating. The percentage of water saved is shown by table 3.

The allowances which have been made for the steam used by the feed pump are based on carefully conducted tests of the feed pump and heater which show that this feed pump when running with saturated and fairly wet steam required for its operation 2 per cent. or less of the weight of steam generated by the boiler. The pump, therefore, uses 2 per cent. or less of the heat required from the fire by the saturated steam locomotive, but in the case of superheated steam locomotive the feed pump will re-

Table 1—Heat Saving Due to Feedwater Heater.

Assumed steam pressure in branch pipe, lb. per sq. in.	200	200	200	200

Heat saving in locomotive with heater as compared to injector operation, per cent.	15.0	12.75	13.94	11.80
Heat required, per cent.	87.0	89.25	87.81	89.95
Heat saving as compared to injector operation	13.0	10.75	12.2	10.05

quire but about 1.75 per cent. of the heat from the fire of the locomotive because of the greater heat required to generate the superheated steam. The tabulation is based on steam leaving the branch pipe at 200 lb. pressure with 150 deg. superheat in the superheated steam locomotive and gives value of the heat saving, water saving, and percentage of exhaust steam required by the heater for tender-water temperatures of 40 and 70 deg. respectively. The term "heat content" is used to express the amount of heat in the water or steam above that in water at 32 deg. fahr. temperature.

From the tabulation it will also be noted that in the case of the feedwater heater for the locomotive, because of its comparison to injector operation, it is not possible to apply the usual short rule customary in stationary practice stating that a certain number of degrees of heating of the feedwater results in 1 per cent. heat saving, but rather that it is more exact to state, assuming the conditions of the table, that in the saturated steam locomotive, after the first 23.8 or 23.2 deg. heating, each 11.9 or 11.6 deg. of heating represents 1 per cent. heat saving, and that in the superheated steam locomotive after the first 22.3 or 21.8 deg. of heating each 12.8 or 12.5 deg. of heating represents 1 per cent. heat saving, the first figures in each case applying with 40 deg. and the second figures with 70 deg. water temperature.

European practice, as far as the author is informed, involves the use of tubular heaters differing only in details of their construction and discharging to the track the water condensed from the exhaust steam in the heater, thus losing both this water and its heat, necessarily with some additional steam that must be blown through the heater to prevent it becoming air-bound. These locomotives require 2 per cent. more water than when operated with the injector because of the steam used by the feed pump and discharge to the track from 15 to 18 per cent. of this with from 2.6 to 1.8 per cent. of the heat of the saturated and 2.4 to 1.6 per cent. of the heat of the superheated steam locomotive in the water alone for 40 and 70 deg. water respectively. There are a few surface heaters in operation on locomotives in this country in which this water is saved by pumping it back to the tender through filters to remove the oil, but in doing so approximately 80 per cent. of its heat is lost by radiation from the tender. This loss of heat from the locomotive with the surface heater does not count directly against the coal saving since it is supplied by the exhaust steam, but it does count indirectly since it decreases the amount of exhaust steam left available for the draft. The open heater is more economical in the use of exhaust steam and leaves more available for the draft with the possibility of lower back pressure and saving because of this.

The locomotive with the open heater or the surface heater saving the water condensed from the exhaust steam requires the extra 2 per cent. steam to operate the feed pump, but from 15 to 18 per cent. of this 102 per cent. is recovered, so that the net water saving is from 13.3 to 16.4 per cent. respectively for the assumed summer and winter conditions as compared to injector operation.

Coal Saving Based on Water Evaporated

To combine these results with the second factor in order to obtain the coal saving based on water evaporated it is necessary to consider particular locomotives since the second factor involves the change in the efficiency of the boiler with varying boiler capacity. For this purpose the curves of Fig. 3 have been prepared. The curves on the left marked A are on the basis of 10 per cent. heat saving; those on the right marked B on the basis of 12 per cent. heat saving. The upper solid curves marked "Injector" are test plant results of a Consolidation, Atlantic, and Mikado type locomotive respectively, and show the total amount of water evaporated per hour against dry coal fired. The dotted curves marked "Heater" for each of these three locomotives show the amount of water that would have been evaporated by the same amount of coal with a feedwater heater reducing by 10 per cent. respectively the amount of heat required to evaporate the water and superheat the steam. The vertical distances between the solid and dotted curves represent the amount of coal saved and these quantities are shown in the lower set of curves. This lower set of curves, therefore, shows the coal saving based on water evaporated due to the feedwater heater that follows a reduction of 10 per cent. and 12 per cent. respectively in the amount of heat necessary to evaporate the water and superheat the steam. These curves show that the feedwater heater attached to a locomotive will effect a coal saving beginning at low capacities practically identical with the heat saving, or the coal saving which we have been accustomed to in stationary practice, but which increases at first gradually and then more rapidly as the capacity of the locomotive is increased, reaching values twice or more than twice these figures as the maximum capacity of the locomotive is approached.

It would be difficult to credit this result were it not warranted theoretically by the second factor mentioned above, and had it not been confirmed in test plant results with a wide margin to spare. A study of the upper curves in connection with the lower curves of both figures will show that the very great coal saving possible is accompanied by an increase in steaming capacity due to the feedwater heater and that it should be possible to work the locomotive with the heater at greater steaming capacities than are possible with the injector but how much greater would depend largely on the particular locomotive.

Referring to the lower set of curves of Fig. 3 and assuming that the Consolidation locomotive would be operated normally at a steaming rate of say 25,000 lb. per hr., it is noted that the 10 and 12 per cent. heat savings assumed as summer and winter conditions would result in 14 and 16.6 per cent. coal savings respectively. Assuming that the Atlantic type locomotive would also normally be operated at a steaming rate of 25,000 lb. per hr., the coal saving would be 12.8 and 14.5 per cent. respectively. Assuming that the Mikado locomotive is hand fired and operated at a steaming rate of 37,500 lb. per hr., the coal saving would be 12 and 14.2 per cent. respectively.

Table 2—Exhaust Steam Required For Heating

Assumed tender water temperature, deg. fahr.	40	70
B.t.u. required to heat one pound of feedwater to 215 deg.:		
from 40 deg.	175	....
from 70 deg.	....	145
Heat content of exhaust steam assumed at 7 lb. pressure. B.t.u. per lb.	1157	1157
Heat content of water at 215 deg. B.t.u. per lb.	183	183
Heat given up by exhaust steam in condensing from 7 lb. pressure to water at 215 deg. B.t.u. per lb.	974	974
Exhaust steam required to heat one pound of cold feedwater, per cent.	18	15
Exhaust steam to heater from feed pump, per cent.	2	2
Exhaust steam from exhaust ports of locomotive required by surface heater, per cent.	16	13
by open heater, per cent.	13.8	11.5

On the other hand, it is altogether possible that advantage should be taken of the feedwater heater either in increased speed or increased hauling capacity and the same amount of coal burned with it as would have been burned if the locomotive had operated with the injector. In this case, the summertime 10 per cent. heat saving would result in a

$$\frac{100}{100 - 10}$$

per cent. steaming capacity or 11.1 per cent. increase; and the 12 per cent. heat saving would result in a

$$\frac{100}{100 - 12}$$

per cent. steaming capacity or an increase of 13.6 per cent. But as compared to injection operation at this increased steaming capacity the coal saving in the Consolidation locomotive would be 15.5 and 19 per cent., in the Atlantic locomotive 13.3 and 15.5 per cent., and in the Mikado locomotive 13 and 15.3 per cent. respectively.

The feedwater heater does not appear to as great advantage in the Mikado locomotive as in the other type locomotives because it is not as fully loaded.

If the Mikado locomotive was operated at a steaming rate of say 50,000 lb. per hr., the assumed 10 and 12 per cent. saving would have resulted in a 15 and 17.3 per cent. coal-saving respectively, and if advantage had been taken of the feedwater heater for the increased capacity burning the same amount of coal as with the injector the coal saving would have been 18 and 21.2 per cent. respectively.

Coal Saving Based on Indicated horsepower

Any modification which the third factor makes in the combination of the first two factors as shown in Fig 3, leading up to the coal saving per indicated horsepower, must be but slight and depend on the particular locomotive. Saturated steam locomotives should show a further gain of a few per cent. from reduced back pressure. Test plant records show some reduction in this back pressure in superheated steam locomotives accompanied by a reduction in superheat and indicate that, at least until further tests are made, this factor should not be considered for superheated steam locomotives.

The curves of Fig. 4 are test plant results of a Mikado locomotive, comparing its operation with the injector and with the feedwater heater described in this paper. Table 4 shows the heat recovered by the feedwater heater and Table 5 the coal saving and increase in efficiency. They show a coal saving curve of the same general character, but slightly higher than the curve for the Mikado locomotive of Fig. 3, based on water evaporated, although the tests were made under practically identical operating conditions as to temperatures and pressures.

The coal-saving curve of Fig. 4 has been reproduced in Fig. 5, and a curve added showing the reduction in the amount of heat required to evaporate the water and superheat the steam, because of the heater. The cross-hatched area above this curve shows the additional saving presumably all due to the better efficiency of the boiler with the reduced amount of heat required from the fire because of the heat recovered by the heater.

Exhaust Steam Available for the Draft

The question has been raised as to whether the exhaust steam taken from the locomotive by the feedwater heater would cause trouble with the draft. This question could be analyzed from the partly theoretical curves of Fig 3, but as actual operating conditions are of more interest, curves have been added to Fig. 5 showing the total exhaust steam taken by the heater and the exhaust steam taken from the exhaust ports of the locomotive. The distance between these two curves represents the exhaust steam furnished by the feed pump to the heater. It is noted that the curve of exhaust steam taken from the exhaust port is below the curve of coal saving. The feedwater heater, therefore, reduced the amount of coal burned at a greater rate than it reduced the amount of exhaust steam, so that there was surplus of exhaust steam left available for the draft and no necessity for reducing the size of the blast nozzle and consequent possibility of reduced back pressure in the locomotive cylinders because of this heater. For instance, at 2,000 i.h.p., the reduction in the amount of coal burned was 18 per cent., and in the amount of exhaust steam, 12½ per cent. As compared to injector operation, 82 parts of coal had to be burned and 87½ parts of exhaust steam were left available for the draft to burn it.

Table 3—Water Saving Due to Feedwater Heater

Steam for locomotive cylinders, per cent.	100	100
Steam required for feed pump, per cent.	2	2
Water required by locomotive with surface heater discharging water condensed from exhaust steam to track, as compared to injector operation, per cent.	102	102
Exhaust steam condensed in heating feed water, per cent.:		
0.18×102	18.4	...
0.15×102	...	15.3
Water required by locomotive with open heater or surface heater saving condensation from exhaust steam compared to injector operation, per cent.	83.6	86.7
Water saving, per cent.	16.4	13.3

Table 4—Heat Recovered by the Feedwater Heater.

Test No.	1	2	3	4
Steam to engine, lb. per min.	314.5	492.8	599.1	757.3
Steam to feed pump, lb. per min.	7.4	10.5	12.5	14.6

With heater	7.6	8.0	8.6	7.8
Increase in efficiency with heater, per cent.	8.5	19.4	28.3	44.4

Conclusions

The feedwater heater on the locomotive may be used to reduce the coal and water consumption working the locomotive at the same capacity as with the injector or to increase the capacity of the locomotive, or partly for both, as occasion demands. It will save coal and water all the time, and permit of increased capacity when needed.

The feedwater heater might be considered as alternate to large size of locomotive boiler and grate as a means to coal economy, if for any reason both are not considered advisable or possible for still further economy. This feature is well illustrated in Fig. 3, where it is noted that the Consolidation locomotive with an open heater gives more steam per pound of coal burned than the Mikado locomtive without a heater up to 2800 lb. of dry coal fired per hr., with the 10 per cent. heat saving, and up to 3000 lb. per hr. with the 12 per cent. heat saving. Test plant records show the Consolidation with heater burns less coal per indicated horsepower than the Mikado without heater up to a still greater rate of coal fired. The smaller amount of coal burned by the Consolidation locomotive at terminals and its lower first cost and maintenance cost favor it still further in the comparison.

Viewed from the standpoint of coal and water saving, the adoption of the heater becomes a question of interest on first cost, depreciation and maintenance cost against these savings. Viewed from the standpoint of increased capacity, the question becomes one as to whether the feedwater heater does not offer increased capacity at the lowest first cost, especially if, as in the case of the comparison of the Consolidation locomotive with and the Mikado locomotive without a heater, the adoption of the heater permits of the use of a simpler and less costly type of locomotive.

The feedwater heater offers a solution of the pressing problem of these times, when so many fairly old and small locomotives have outgrown their usefulness because they are not large enough for present-day demands. The feedwater heater will not only increase the capacity of these locomotives, or what might be called their economical operating capacity, at a comparatively low cost and with little change in them, but it will also show a larger percentage of coal saving because of their full loading than would be obtained with present-day larger locomotives.

The feedwater heater offers the peculiar advantage of being of most assistance to the locomotive just at the time when the locomotive needs assistance. It offers its greatest saving in fuel or increase in capacity in the winter time, and these advantages are not ef-

fected by reduced steam pressure or superheat, but continue in spite of them and at a proportionately greater rate.

The study of the subject of the feedwater heater for the locomotive that has been reviewed in this paper has resulted in the adoption of the open-feedwater heater as a type. It has been developed into a unit with the pump, so that it can be attached to the locomotive at minimum expense. These units have been thoroughly tested both on the test plant and on the road, and every confidence is felt in their ability to meet the severe requirements of locomotive service, and to effect the maximum possible saving of fuel and water with a minimum amount of attention from the crew.

STANDARDIZATION OF STRUCTURAL SHAPES

On the entrance of the United States into the war with the Central Powers there came a demand for immediate increase in ship construction which, in turn, meant increased production by the steel mills. To increase production to the minimum and to simplify order practice, a conference of steel makers was held in Washington on July 2, 1917, at which was adopted American standard practice for structural steel for ships.

The result of this action proved distinctly beneficial both to the mills and the shipyards, but was not followed immediately by a standardization of and a reduction in the number of structural shapes used at the yards, and in consequence the Emergency Fleet Corporation undertook an investigation to ascertain definitely the number of structural shapes used in shipbuilding and the possibility of their standardization and reduction in number. As an outcome of these investigations carried on by Mr. Fred T. Llewellyn in the Division of Steel Ship Construction under Daniel H. Cox, Manager, it became possible to determine what were the sections in most general use and at the same time were brought out clearly the divergencies in the sections rolled by different mills

At a conference of steel makers held in Philadelphia on November, 19, 1918, inasmuch as the British standard sections of ship channels and shipbuilding bulb angles appeared to be better adapted to economical manufacture than the American standard sections and inasmuch further as the new rolls which had been turned in recent years to produce sections conformed in general to British standards, it was decided that therefore American standard sections should be discontinued and that rolls not then to British standards be redressed at as early a date as possible to roll such sections as closely as possible to British standards and this particularly in view of the further fact that the adoption of British standard sections would enable American mills to compete on an even basis for ship steel wherever utilized in shipyards, either at home or overseas.

The British standard sections thus adopted as American standards were those adopted by the British Engineering Standards Association as published in 1903, and it was not known that this Association had undertaken a revision of the British standard sections in 1913, work on which, however, had been suspended by reason of the war activities. When, however, through the trade press, information as to what had been done in the United States came to the attention of the British Engineering Standards Association, that Association advised American steel makers as to the situation and later through their secretary, Mr. LeMaistre, expressed their desire to have the American structural trade co-operate with the British Engineering Standards Association in the formulation of common Anglo-American standards for structural shapes.

At the instance of the Association of American Steel Manufacturers, a Sectional Committee on Steel Shapes was organized under the auspices of the American Engineering Standards Committee. This Sectional Committee is composed as follows:

American Bureau of Shipping—Captain C. A. McAllister; David Arnott; John Martin.

American Society of Civil Engineers—J. H. Edwards; J. B. French; H. G. Balcolm.

Association of American Steel Manufacturers—R. B. Woodworth, (Chairman); G. H. Blakely; Geo. E. Thackeray.

Railway Car Manufacturers' Association—A. E. Ostrander.

Society of Naval Architects and Marine Engineers—Fred T. Llewellyn; E. H. Rigg; J. W. Stewart.

United States Navy — Commander C. M. Simmers; Lieut. Com. H. D. Rouzer.

The Sectional Committee gave very careful consideration to the entire routine of structural practice in the United States not only as it affects the profiles of structural shapes themselves, but also as regards methods of order practice, calculation and publication of weights, areas and properties, etc., with the idea to insure as far as possible a complete accord between makers and users wherever the sections rolled in English - speaking lands were used. At its meeting held on April 27, 1920, it formulated its recommendations for submission to its sponsor organizations, to the American Engineering Standards Committee and to the British Engineering Standards Association as a basis for common Anglo-American standards, and its conclusions are now to go before these organizations for further discussion and endorsement. The essential features of these recommendations are:—

1. The adoption of the decimal system for the expression of dimensions, thicknesses and other elements of order practice.

2. The adoption as an Anglo-American standard of the standard order practice adopted by the Association of American Steel Manufacturers on February 20, 1920, under which structural shapes are to be ordered by weights per foot and not by thickness.

3. The adoption as an Anglo-American standard of American standard practice as it relates to ranges of thicknesses, methods of computation and methods of publication.

4. The adoption of definite ranges in thicknesses of angles and other structural shapes, under which are established two zones of variations between minimum and maximum thicknesses. Under .60-in. thick variations are fixed at four one-hundredths inch (0.04-in.) and above .60-in. thick at eight one hundredths inch (0.08-in.)

5. Included in the list of angles is an equal angle (9x9) and four unequal angles (8x4, 9x4, 9x6 and 10x4) which are not now rolled in United States, but are subject to the considerations which weigh with manufacturers when new rolls are contemplated.

6. The adoption of a new line of bulb angle sections as proposed by the British Engineering Standards Association that are recommended on account of their greater efficiency as compared with present British and American standards.

7. The adoption of a single line of channel sections with a 5 deg. flange taper to displace the present two American lines, the structural line with its flange taper 9 deg. 27′ 42″ and the shipbuilding line with its flange taper of 2 deg. This line of channel sections is not quite in accord with that proposed by the British Engineering Standards Association, but is believed to be more suitable to the requirements of the American trade and better proportioned.

8. The adoption of a new line of beam sections to take the place of the present American standards adopted in 1896. These sections have wider flanges than present American standards and do not agree very closely with the British proposals, but are believed by the Sectional Committee to be more nearly in accord with the recent developments in the fabrication of buildings and bridges.

A recent communication to the French Academy of Sciences, states that coal has been discovered in the region of Port Gueydon, French North Africa. This coal appears to belong to very extensive beds lying in the region mentioned. Analysis taken have revealed the following composition:—"Moisture, 1.05 to 1.15 per cent.; ash, 37.15 to 53.65 per cent.; volatile matter, 8.05 to 12.27 per cent.; fixed carbon and sulphur, 37.25 to 49.45 per cent; the calorific value varies from 3960 to 5390 calories.

The Council of Action

THE creating of what is known as a Council of Action by the leading trades unions in Great Britain, with the avowed object of dictating to the Government its policy on certain questions of national importance, creates, as Mr. Lloyd George plainly states, "the most formidable challenge ever given to democracy." There can be no doubt that the people of Great Britain generally are war weary, and not labor alone. The greatest beneficiaries of the war were the trades unionists, and some of the capitalists, though not by any means all. It is the great middle classes who suffered the most and got nothing at all out of it who would probably be the most unwilling to see their country embarked on another period of war. Their voice, however, is not heard above the clamor made by the representatives of organized labor, which, after all, is by no means a majority of the community, but, on the other hand, a relatively small portion. Organized labor in Great Britain has, since the war, been frankly out to get everything it could possibly extort, and has not been afraid, in this endeavor, to attempt the complete paralysis of the country. The great transportation strike should have taught their representatives that when they go in opposition to the general public they are comparatively powerless, and it is quite possible that in making their threats of a general strike in the event of Britain taking action in Poland, they did so with their tongues in their cheeks. As a matter of fact, the British Prime Minister says that the aims of the Government and the aims of the Council of Action are practically the same, but he plainly and positively states that were they not, "dictation would be resisted by all means in the power of the Government." Trades unions can serve an excellent purpose, and have been instrumental in making life a more pleasant thing for the trades unionist. When they start to assume the role of the Government it is time to call a halt. While every right-minded person wishes to see labor, both organized and unorganized, get all the good out of life that it is possible to obtain, no sane person wishes to see any minority of the people holding a club over the rest. Lloyd George is to be congratulated on his uncompromising stand against such coercion.

The Engineer's Opportunity

THE organization of the Federated Engineering Societies at their recent conference at Washington, D.C., is certainly a step in the right direction.

About 75 branches of the engineering profession were represented, these including Civil, Mechanical, Mining, Electrical, Sanitary, Heating, Marine, Agricultural, Radio, Refrigerating, Fire Protection, Industrial, Automotive, Military Engineers, Architects and Geologists, etc.

The need of such a body has been felt for years, but the problem was to successfully affiliate the various interests. The action taken at Washington has removed the only remaining nigger in the woodpile.

The object of this newly formed body is both ambitious and essential. They desire to raise the standing of engineers generally, and to teach the public how much they really depend upon the engineering profession. Any society, club or organization, the chief object of which is the advancement of the knowledge and practice of engineering and the application of applied sciences, and which is not organized for commercial purposes, is eligible for membership.

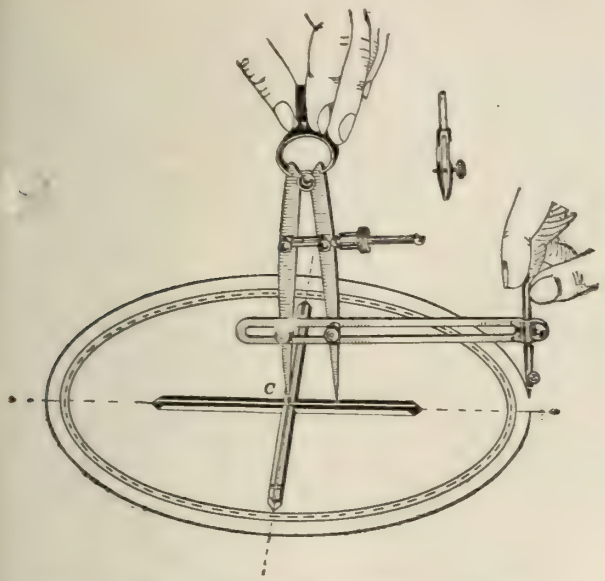
The success of this society, as we see it from our side of the line, depends entirely upon the engineers themselves. With proper support this body should grow to be a powerful influence and will form the official mouthpiece, so to speak, for engineers all over the country.

To our mind the forming of this society should be greeted with great enthusiasm by engineers in general and they should rally to its support. An opportunity such as this affords is not to be treated lightly. We will watch with interest the development of the organization, and once more emphasize the necessity of every engineer becoming a live member and actual booster.

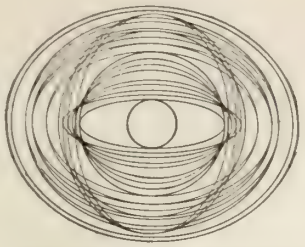
—Thomas in the Detroit "News."
"City folks get themselves into the durnedest messes."

REID ELLIPSOGRAPH

Daniel C. Reid, 2717 N. Croskey Street, Philadelphia, Pa.. has placed on the market what is known as the Reid Ellipsograph. This instrument is claimed to draw all kinds of ellipses or ovals, from 1½ in. up to 12 in. major axis, and describes a perfect ellipse in one operation.



THIS VIEW SHOWS THE INSTRUMENT IN USE.



THE WORK ACCOMPLISHED

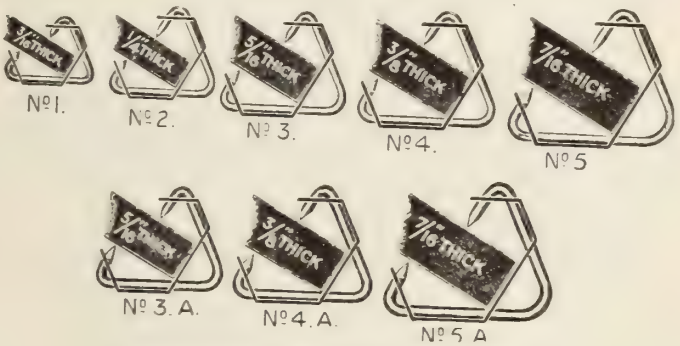
The instrument is provided with pen and pen parts, and can also be used for drawing circles up to 12 in. diam. It can also be used as an ordinary divider. This announcement will no doubt appeal to draftsmen, designers, illustrators, architects, etc. To illustrate its construction we show the illustrations herewith.

UNIVERSAL BELT FASTENERS

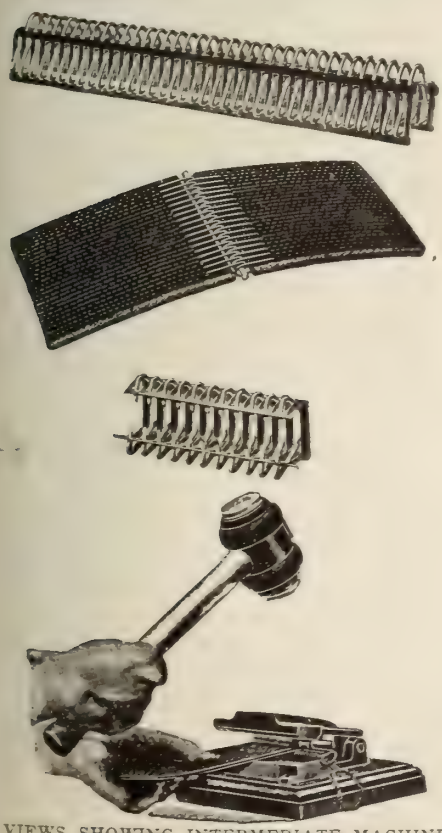
An improved type of belt fastener, known as the "Universal," has been placed on the Canadian market by the Climax Company, of 244 Lemoine Street, Montreal. These fasteners are the result of careful study and exhaustive experiment on the part of the makers, and are universal in character. They are equally efficient in rubber, balata, leather or cotton belting, and are made in six-inch lengths, of sizes varying to take belts from 3-16 to 7-16 inch in thickness. The individual hooks are held in position by a metal frame which retains the hooks in the same relative position all the time the hooks are being forced into the belt. When the hooks are flush with the belt the frame slips off freely. The fasteners are made in two gauges of wire, the larger sizes being adapted to meet the requirements of the user who has extra heavy belts running over small pulleys.

On the intermediate fasteners the wire can be laced into the belt with a simple hammering tool, economically and efficiently. For the larger sizes, a special lacing machine is preferable. On the smallest sizes, the lacing can be performed by using a hammer and a wooden block, the metal frame assuring perfect alignment during the operation. The great advantage of the metal frame is that it prevents the hooks from twisting to one side or the other while being forced into the belt. The fasteners are made with a series of hooks having long and short legs, the short legs entering the belt on the pulley side, this method minimizing the metal contact on the pulley and reducing the possible slip. The hooks do not meet in the belt, but are individually staggered, thus increasing the effective pull.

The fasteners can be cut to any desired length without fear of wasted ends, as the metal frame keeps the pieces intact. A pair of narrow scissors are provided for cutting the metal frame.



VIEW SHOWING THE VARIOUS SIZE HOOKS.



VIEWS SHOWING INTERMEDIATE MACHINE AND OTHER DETAILS.

THE HEAVIER TYPE MACHINE.

We have received Bulletin B-410 of the Yarnall-Waring Co., describing the Yarway seatless and Yarway double tightening blow-off valves. There is an interesting diagram showing the cost of leaky blow-off valves. This shows by means of a curve loss in water and coal in dollars per month and per year, and water loss in thousands of gallons per month. These valves are constructed to conform to the A. S. M. E. standards. The double tightening valve was originally made to use in conjunction with the Yarway seatless valve in places where the boiler laws require the use of two valves. Anybody interested in blow-off valves can obtain a copy of the bulletin by requesting one from the makers, Yarnall & Waring Co., Chestnut Hill, Philadelphia.

Want To Get Heat.—A strong committee has been appointed by the Board of Directors of the Chamber of Commerce of Chatham, to meet representatives of the Chatham Heating Co. The object of the committee is to try and prevent a repetition of last year's experience, when business suffered to a considerable extent due to a lack of heat, which it is claimed the company failed to supply.

TRADE GOSSIP

The Canadian Pacific Railway Company announce the apopintment of Mr. F. S. Rosseter to be acting Superintendent, Chapleau Division, with headquarters at Chapleau, vice Mr. W. R. Boucher, who has received a month's leave of absence.

Want To Export Coal. — The chairman of the Dominion Railway Commission is receiving many applications for permission to export coal. There has been an order against the export of any coal from August 1st, and the applicants claim that they had the contracts made and vessels chartered to carry the coal before the order came out. They, therefore, claim that they should be allowed to export those orders.

Car Shops for Toronto.—It is understood that representatives of car-building firms have been looking over the ground with a view to establishing a street car building shop in Toronto. This is irrespective of the continuation of the Toronto Street Railway's shops for car manufacturing. There is a probability also that the plant of the Dominion Shipbuilding Co. may be utilised for this purpose.

Alberta's Coal Export Increased. — The output of the Alberta mines for the six months ending July 31st was 3,043,940 tons, as compared with 2,068,907 tons for the same period last year. There has been more coal marketed during the six months period than in any corresponding period in the history of coal mining in Alberta. The exportations for the six months show a 50 per cent. increase.

Coal Situation Better.—According to Mr. J. D. A. Morrow, vice-president of the National Coal Association in the United States, and who has just returned from a ten days' trip, the situation is better than it was. Due to the increased car supply, a big increase in the coal shipped to New England and the North-West besides other parts of the country had taken place. The production for last week, he estimated, was about 11 000 000 tons, which is still 1,000,000 tons under the normal requirements.

Hydro Business Last Year. — In a statement made by the Hydro Electric Commissioners, the following figures are given. The number of municipalities taking power has increased in ten years from 12 to 115, and the power distributed from 25,000 to 225,000. There are 12 rural systems, 23 companies, and five Government industries. The total assets at the Falls and in the municipalities amount to $40.693,070 and the accumulated reserves $7,654,370 and the surplus $2,177,934.

Mine Sells Entire Output.—The Blue Diamond Coal Mines at Brule, Alta., have contracted their entire output for the next six months, according to J. P. Bickell. Mr. Bickell is a director of the McIntyre Porcupine Mines, Ltd., which has just purchased the coal mining company. The contract is for the west, and the entire capacity is required, even if it exceeds 2,000 tons per day. The output is at present about 600 tons per day, and it will require over a year to bring the output up to 2,000 tons per day.

Starting in Vancouver.—The Britannia Wire Rope Co., is getting in shape to operate at their plant on Granville Island, B.C. The machinery for most of the plant is now on the way from England. C. H. Gill is the British director, and Robert Gibson, managing director.

Conference in Fall.—The second great Industrial Conference will be held in Canada some time in October or November. An appropriation was made by Parliament at last session to cover the expenses of the conferences, and it is expected that the experience gained at the last conference will result in making this one an even more representative gathering of labor, capital and the general public.

New Rates Contract. — The Special Scale Committee of coal operators and miners sitting in District 18, Calgary, have completed their labors. The agreement is between the Western Canada Coal Operators' Association and District 18, of the United Mine Workers of America. The agreement provides for an all-round increase, and is in force till April next, and retroactive from March last.

Baldwin Plant Ready Soon. — The plant at Ashbridge's Bay will be ready for operation in about three weeks' time. it is expected. There will be a staff of between eight and nine hundred men employed at the beginning, and when the plant has worked up to full capacity it will employ 6,000. A large number of the men are coming direct from the works in Wales and incidentally among these are included some who were in Moscow with the general manager of the plant here, Mr. Cound.

Bounty for Iron Industry.—The Hon. William Sloane, Minister of Mines for the Province of British Columbia, speaking about the possibility of an iron smelting industry in the Pacific Coast Province, pointed out that the present bounty offered by the Provincial Government would amount on a 300-ton plan to something like $1,000,000. He stated that Mr. Fleming, of the Canadian Collieries (Dunsmuir), was looking into the situation, as their company thought of entering into the industry. As to the claim that there would be no market for the product, Mr. Sloan thought there would be no difficulty on that score, as the Pacific Coast could be supplied at prices beyond the competition of eastern furnaces. In any case, he thought the Federal Government could be induced to build extensive car shops for the National Railways at one of the western terminals, which would absorb a large percentage of the output of a 300-ton furnace.

Herbert Johnson, of the Armstrong Whitworth Company of Canada, has been appointed general superintendent of the plant at Longueuil. Lawrence Russell, the general manager, will be in charge of the sales.

Have Bought Factory.—The Dominion Cone Company have sold their factory at 14 Morrow Avenue to Tarbox Bros., specialty manufacturers. The building is of two storey brick, with a basement, the total floor space being 12,500 square feet. The frontage is 40 feet The deal was closed through Robins, Ltd.

Brantford City Engineer.—Mr. Frank Adams, city engineer of Chatham, has been appointed city engineer of Brantford, at a salary of $3,600 for the present year, and $4,000 for next year. Mr. Adams is an old Brantford boy, and well acquainted with the locality, and its special problems. He will take up his duties on September 15th next, succeeding the late Major Harry Jones.

ACCIDENT PREVENTION

Accidents and accident prevention in machine building are discussed in Bulletin No. 256 published by the United States Bureau of Labour Statistics. The booklet gives the result of an investigation to ascertain the frequency and severity of accidents in the machine-building industry, and to study and analyse these accidents in such a way as to supply the information necessary for effective safety work, To this end the report seeks, as far as possible, to locate the accident hazards in particular departments and occupations, to discover the reason and causes for the occurrence of accidents, and to point out some of the more successful methods for their prevention. The investigation was limited to certain selected plants representing the more important classes of product, and covered in all 194 plants. Accident rates are analysed for the industry as a whole, by character of products, and by departments. Inability to speak English as related to accidents, safety organization, direct safeguarding methods in machine building, and machine design as a factor of safety, are among the subjects discussed.

OPTICAL INSTRUMENTS

Optical equipment for the inspection of flat surfaces and the comparison of standards, is a line of tools now being placed on the market by the Van Keuren Company of Boston, Mass. By means of these instruments comparisons can be made to one-half a wave length of light, which for daylight is approximately 0.00001 inch. It is claimed that the working flats of the set will register an accuracy of 0.000005 inch and that of the master flat to within 0.00000025 inch. Full instructions are included with the instruments and the equipment is intended for shop use.

CONE PULLEY BELT SHIFTERS

Speaking on the above subject before the summer conference of the National Safety Council (Engineering Section), Mr. H. E. Somes, electrical engineer of the Chevrolet Motor Co., made the following statements:

At your last meeting, I volunteered to obtain time studies on mechanical belt shifters for cone pulley belts and on the hand method. After going through a number of large machine shops, I was very much surprised to find that, with the exception of an isolated instance, belt shifter devices for cone pulley belts were not used; and due to that fact, and also the short period of time left to investigate this subject, I have been unable as yet to obtain the time studies. One of our factory managers who has a successful belt shifter installed expressed it as his opinion that a green workman can shift cone pulley belts by means of the belt shifter as rapidly as an experienced workmen can shift them by hand—with the additional advantage that in doing so he is safeguarded from injury. However, in my investigations on this subject, I have been convinced of the fact that mechanical belt shifters can be developed that will shift belts on cone pulleys more rapidly than by means of the hand shifting method—much more safely and efficiently and without serious injury to the belt itself. Possibly such shifters have already been developed.

The problem, however, seems to be where should cone pulley belt shifters be required? Such a shifter has its maximum value when it is installed on a machine where belts are shifted many times per day. If a saving can be realized in the workman's time, due to an improved method of shifting belts and the machine itself has a greater capacity, these advantages will become more apparent as the number of belt changes increases. Usually the advantages become of lesser importance as the number of shiftings decreases.

I would submit, therefore, at this time that mechanical belt shifters for cone pulleys are particularly adapted to shop installations where frequent shiftings of the belts from one step cone to another is necessary. Among such installations we find the tool room, the maintenance or the repair shops, and many other types of manufacturing machine shops which can possibly be classified wherein belt shifting is a necessity.

Considering the modern manufacturing machine shop, such as the automobile manufacturing plant, we are struck at once by the fact that belt shifting is very uncommon, and in fact in many cases, if the manufacturer could obtain them, single purpose machines would be [illegible]

In a shop of the type commonly called production machine shop, we find that an individual machine is tooled up for a single job, and that frequently this machine runs several years without having any change made in the method of manufacture or the speed of either feed or spindle.

Illustrating this point, I was in Flint, Mich., recently and went to our plant to see a screw machine which had been fitted with a mechanical belt shifter. I asked the operator what he thought of the shifter in question and how he found he could shift the belt by means of the shifter. He replied that he had been employed on that particular job for approximately eight months; he thought the belt shifter was very satisfactory, but that he never used it to shift belts with, excepting to satisfy himself that the shifter would work. This condition exists throughout that entire plant.

The field where the belt shifter would give greater service would undoubtedly be in a shop not engaged in production manufacturing, but rather where on account of the special nature of the different jobs, wide variations in the spindle speeds are necessary. This would also apply to drill press operations where the step cone pulleys are not on the machine itself and where one is exposed within twelve or eighteen inches of the floor. Drill presses, excepting where they are used over long periods of time on a single operation, require a large number of changes throughout the working day, owing to the different sizes of drills which may be used on an individual job.

While observing a belt shifter at Flint, several days ago, I noticed that it seemed to be very satisfactory in shifting from high to low; but in shifting from low to high speeds, I noted that the belt curled and that it was very difficult to make this shifting. The plant engineer advised me that the shifter had been thoroughly satisfactory until the belt became oil soaked from long use.

In order, however, that we may obtain accurate information as to the advantages of using mechanical belt shifters over the hand shifting method, and also in order that we may know definitely whether a satisfactory shifter has been developed, our company has arranged to conduct a test on several types of shifters. This test will be strictly impartial, and as a result, we hope to learn whether by using a mechanical shifter the belt is injured, and whether the shifters are satisfactory after the belt has become thoroughly oil soaked and very pliable.

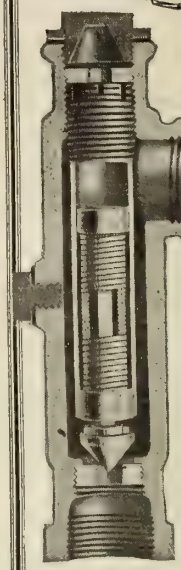
Why Pay $45. For $6. Worth of Iron?



Why pay $1.50, instead of 2¼c a pound for about 286 pounds of superfluous iron in a steam trap? That is literally what you do when you purchase a cumbersome steam trap of the bucket or float type, with its array of troublesome floats, levers, valves, water gauges, bowls, and other unnecessary parts.

The Steam Trap Sarco does everything that the larger, heavier and more complicated traps do. Yet, it has but one moving part and weighs about 6% as much.

STEAM TRAP SARCO

because of its simplicity and light weight, sells for about one-third the price of other makes.

A Sarco saves money in the purchase price as well as in installation cost, for it requires no platform building, no supports, no pit digging. Can be easily and quickly installed at any point on the line.

Let us send you a Sarco on 30 days' trial. If you are willing to part with it at the end of that time, send it back and the trial will cost you nothing.

Write for Booklet J-17 and full information.

15 Sales Offices Backed by the 100% Standard of Quality

THE Canadian Fairbanks-Morse Company Limited reaches out to you through its sales houses and offers the service and satisfaction that is assured by its 100% standard of quality and service.

To be able to turn to an institution that dominates its field in the industrial world is to safeguard the character of the merchandise you buy. To deal with an organizationthat is doing business at your very door puts upon the man you know that "responsibility which is the conscience of business."

Every one of these 15 offices has been established to bring to you the full advantages and benefit that have made The Canadian Fairbanks-Morse Co. Limited a national institution. Here in these offices is offered everything mechanical that your business requires — they centralize your purchasing—group your orders—bulk your shipments and send but one invoice. And when you buy from The Canadian Fairbanks-Morse Co. Limited you are guaranteed the 100% standard of quality and service in product and organization.

Make our nearest office your buying centre—our catalogue is your buying guide —our 100% quality seal your guarantee.

WHY DO YOU ADVERTISE

When You Are Behind In Deliveries ?

THIS seems to be a very natural question, and the answer involves the discussion of a vital policy of this business—a policy that is fundamental.

If we were building a business for to-day our policy would vary from day to day with the temporary changes with which every business has to contend.

But we are building for the time to come and we hope that this business will become many times greater than it is to-day. Without the proper foundation it would undergo violent changes dependent upon temporary national, local or even imaginary conditions.

If we should permit ourselves to become inflated with self-confidence when business conditions are favorable, restricting our selling and advertising activities, and go down in the dumps when conditions are not so favorable, this business would not amount to any more than the existing conditions would make of it.

We say right now, without reservations, that we hope, regardless of how aggressive and efficient our manufacturing department may be, that it will never be able to catch up with our selling organization.

If our efforts should be halted in the middle of the road in times of liberal buying to wait on the manufacturing department, there might come a time when the manufacturing department would have to suspend operations while waiting on the sales organization.

With such a policy we would be running around in a circle, disorganizing one day and reorganizing the next.

The greater the demand for our product, the quicker the turnover for merchants; and the more frequent the turnovers, the larger is the volume of profit.

In this business advertising is a sales policy—the same as our policy of maintaining a sales organization—and we might as well consider the elimination of one as the other. Neither will be eliminated, as this business needs both if we are building for the future.

We hope the idea will never creep into this organization that there will be any let-up in aggressive methods, which might suggest that when business is good there is no occasion for work and when business is poor it is too hard to get.

We constantly have in mind that the American people are much more concerned in their own affairs than in ours, and if we should restrict our selling and advertising activities they will begin to forget us—and this would be our fault.

We are going ahead with the idea of increasing the present momentum in favor of our goods; and if conditions should turn face about, our dealers and ourselves will be in a better position to hurdle obstacles than if we originated a policy for each condition as it arose.

DEPARTMENT OF LABOUR

Ontario Government

Minister: Hon W. R. Rollo **Deputy Minister: W. A. Riddell, Ph.D.**

NOTICE TO STATIONARY AND HOISTING ENGINEERS AND STEAM PLANT OWNERS

Everyone operating a **Stationary** steam plant of 50 B.H.P. or over, and everyone operating a **Hoisting** steam plant working at a pressure of 20 pounds or over, irrespective of horsepower and used for hoisting in structural operations or excavating purposes, in the Province of Ontario, must hold a certificate from the Board of Stationary and Hoisting Engineers. Application forms will be forwarded upon request.

After January 1, 1920, all stationary steam plants in the Province of Ontario must be registered with the Board of Stationary and Hoisting Engineers. Application forms will be forwarded upon request.

All applications should be mailed to the Chairman of the Board. W. C. McGhie, Department of Labour, 15 Queen's Park, Toronto.

NOTICE TO MANUFACTURERS, DEALERS AND USERS OF STEAM BOILERS

All steam boilers built in, or entering, the Province of Ontario, and boilers exchanged or repaired, are subject to Government Inspection as prescribed in the Steam Boilers' Act, 3 George V., ch. 61.

Before any work of repair or alteration is commenced on any boiler, notice must be sent to the Department stating the nature and extent of the repairs or alterations proposed to be made. If the Chief Inspector should consider such repairs or alterations of an extensive character, the boiler must be inspected in accordance with the Regulations by an Inspector authorized under the Act.

All communications should be addressed to the Steam Boiler Branch, Department of Labour, 15 Queen's Park, Toronto. D. M. Medcalf, Chief Inspector of Steam Boilers.

MONCRIEFF'S

"UNIFIC" GAUGE GLASSES

The British Navy uses "Moncrieff's" "Unific". It is the kind that lasts.
It is a special feature of the "Unific" that it does not readily corrode; resists extreme changes of temperature and withstands the highest working steam pressure. In consequence it has a long life, justifies a higher price than the soda lime glasses, and is, indeed, the more economical purchase in the end.

THE ANDERSON
MODEL "D" STEAM TRAP
Allows No Escape Of Live Steam.

The valve is always locked with at least three inches of water, thus the escape of live steam is rendered impossible.

The **Anderson** will lift water at any back pressure five pounds less than the pressure at the trap:

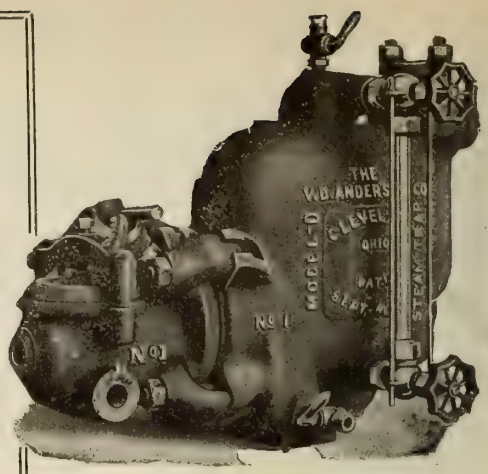
A strainer and sediment chamber prevents sediment and scale from getting into the valve.

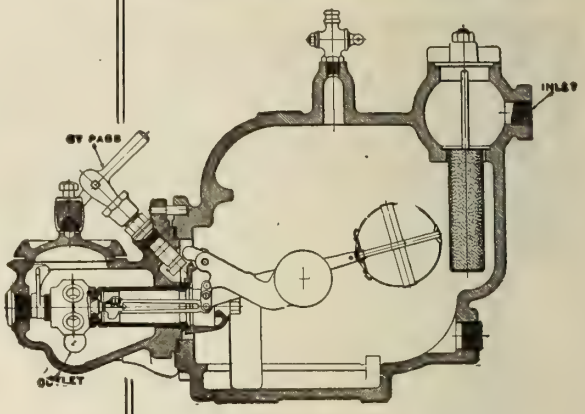
To ascertain whether the trap is working properly, a glance at the gauge glass, fitted to the trap, is sufficient.

The valve and valve seat can both be removed without breaking a steam joint or pipe connection.

The **Anderson Model "D" Steam Trap** is accurate in every detail. Built of materials best suited for the purpose. Every part interchangeable.

Full particulars of these and other points will be forwarded immediately upon receipt of your request.



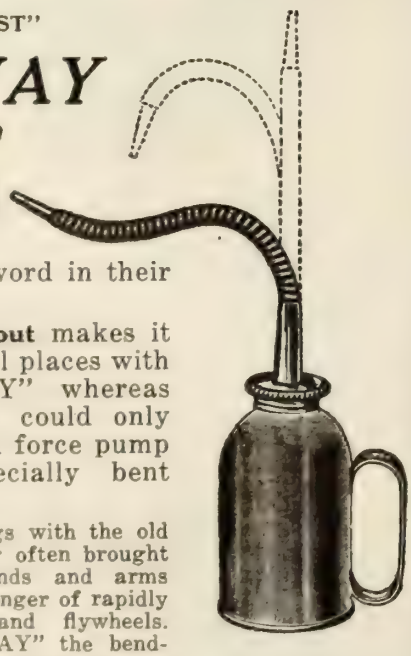


The V. D. Anderson & Company

1935 West 96th St., Cleveland, Ohio.

"SAFETY FIRST"

ALL-WAY
RAILROAD
OILERS



are the latest word in their line.

The **flexible spout** makes it possible to oil all places with one "ALL-WAY" whereas previously they could only be reached with force pump cans with specially bent spouts.

Lubricating bearings with the old straight spout oiler often brought the engineer's hands and arms very close to the danger of rapidly revolving gears and flywheels. With the "ALL-WAY" the bending of the spout removes this danger. Sizes No. 4, 1 pint—10 in. spout. No. 5, 1 quart—11 in. spout.

If your dealer cannot supply you write us.

We also manufacture the well-known "All-Way" Oil Can—saves you 50% of your oil bill.

The Design of Moore Steam Turbines Prevents Steam Leaks

Ample surfaces at the joints have been provided to prevent leakage of steam—also the number of vertical joints have been reduced to a minimum. In a turbine having numerous vertical joints it is almost impossible to prevent leakage and consequent loss of efficiency in operation.

The careful designing to prevent all steam leakage is but one feature of Moore Steam Turbines. Send for our booklet. It explains fully the others.

Moore Steam Turbine Corporation
Wellsville New York U.S.A.

HOMESTEAD VALVES

Positive-Acting Quarter-Turn Valves

Homesteads are "positive-acting" in each position. When open there is a straight, unobstructed flow. When closed they are positively tight. All Homesteads are constructed with the patented Homestead principle, which locks the valve tightly to the seat when closed.

One-quarter of a turn only is necessary to open and close Homestead Valves. Adopt them. You'll save time, trouble and expense.

Our catalog contains some interesting information.

The Safe Way

Vigilant Water-Feed Regulators

There need be no worry on the part of you or your men in feeding boilers.

The "Vigilant" will automatically hold the water level at middle gauge—the safe, desirable point at which the boiler contains the maximum steam liberating surface.

Write for full particulars to-day.

The Chaplin-Fulton Mfg. Co
28-34 Penn Avenue, Pittsburgh, Penn.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract.

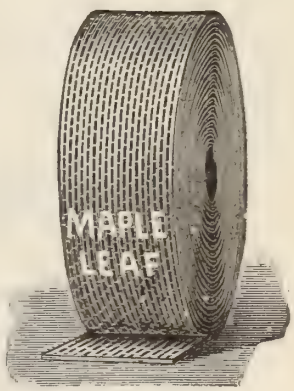
Dominion Belting Company, Limited
Hamilton, Canada

Sole Manufacturers of the celebrated "MAPLE LEAF" Brand Stitched Cotton Duck Belting and Belt Dressing.

The demand for our products has steadily increased because the standard of quality has been maintained.

We make only one grade, the best that can be produced.



"MAPLE LEAF" is the strongest, truest running, most economical and efficient belt on the market for transmission of power, conveying, etc.

Being thoroughly waterproof it is suitable for running in wet or dry places. **"MAPLE LEAF"** Belt Dressing is different to others offered in that it is equally good for all kinds of belting, leather, rubber or Balata, as well as our own make.

Write us for prices, and if desired we will be pleased to furnish samples and further information.

A trial order will convince you of their utility.

ROBB

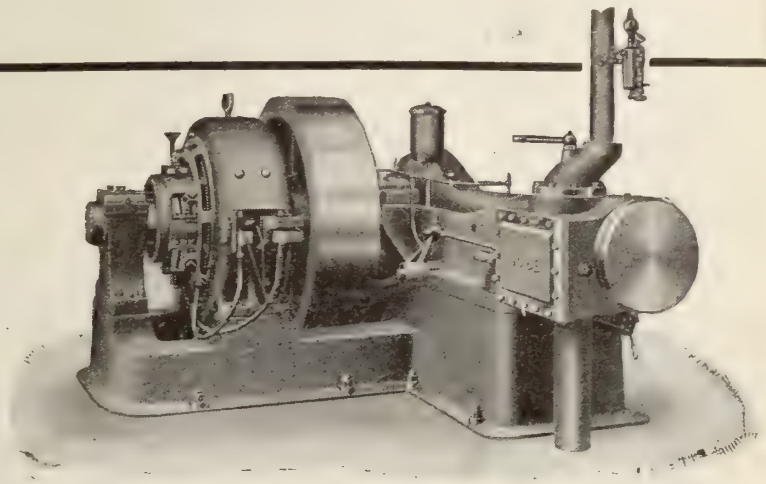
For Quality Equipment

POWER PLANTS

We specialize in the design and construction of power plant equipment. Our engineers are prepared to investigate your problems and advise on the most economical machinery for your needs.

We can supply Corliss, Slide-Valve, Vertical, Horizontal, Simple and Compound Engines, and Water tube, Return tubular, Improved Scotch Marine, and Portable Boilers.

Robb Equipment is known to engineers and power plant superintendents for its long and dependable service, standard quality and modern design. When you are in the market—remember it will pay you to purchase equipment that has won the confidence of leading engineers.



Robb Engineering Works Co., Ltd.

Amherst, N.S.

Montreal Office: 16 Cathcart Street

Toronto Office: 20 Victoria Street

'Bishop's Adamant' Gauge Glasses

Will resist all Steam Pressure and Variations of Temperature.

REFLEX GAUGE GLASSES

Annealed and Hardened for
LOCOMOTIVES, STEAM WAGONS, MARINE AND STATIONARY BOILERS.

Adamite Gauge Glass Rings. Glass Tubes and Rod

S. & C. BISHOP & CO., St. Helens, Lancashire.

LADD

WATER TUBE BOILER

The Ladd Water Tube Boiler

is built in all sizes and for any of the many methods of firing—stoker, oil, gas, powered coal, etc.

Write our engineering department about your requirements.

Catalogue on request.

THE GEORGE T. LADD COMPANY

First National Bank Building, Pittsburgh, Pa.
Chicago Office: 528 McCormick Bldg.

FOR REMOVING SCALE

from Babcock, Stirling and other Water-tube Boilers and Evaporators, also for Lancashire Boiler Scaling and Rust Removing—there is no tool made to equal my

'SKATOSKALO'

Pneumatic Tube-Scaling Tool.

Simple, strong, speedy, reliable---these words describe its efficiency

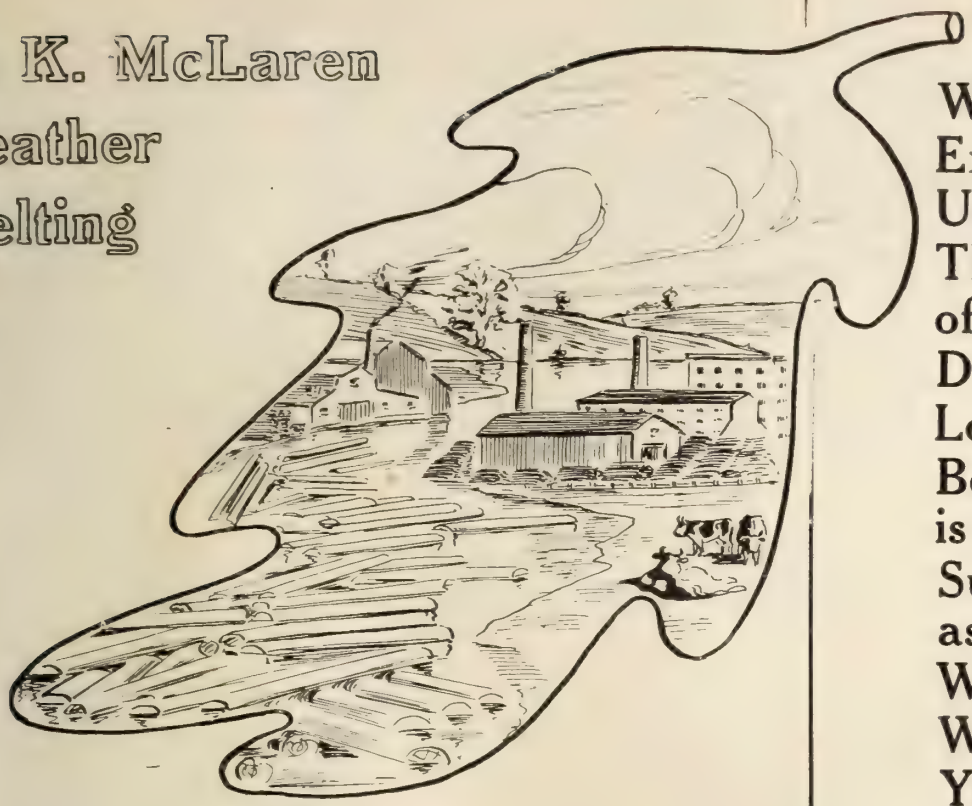
D. K. McLaren Leather Belting



What Experienced Users Think of D. K. McLaren's Leather Belting is a Sure Guide as to What It Will Do For You!

Get in touch with some of these users. Write us; we'll gladly furnish you with some names and addresses.

No secret is made of the process by which McLaren Leather Belting is made. In fact we wish everyone to know the quality of each feature.

The Hide. The hides are cut from the **backs** of the choicest steers. The back is the strongest part and of even strength and elasticity throughout.

The Tanning. The genuine British Oak Tanning Process gives McLaren's Belting that mighty toughness. No better method is known for treating leather for belts.

The value of these two features is apparent the moment the belting is installed. Slipping reduced to a minimum, thus saving considerable power, and lack of stretch—these are the results.

GENUINE OAK

Belting trouble ends where D. K. McLaren's Belting begins

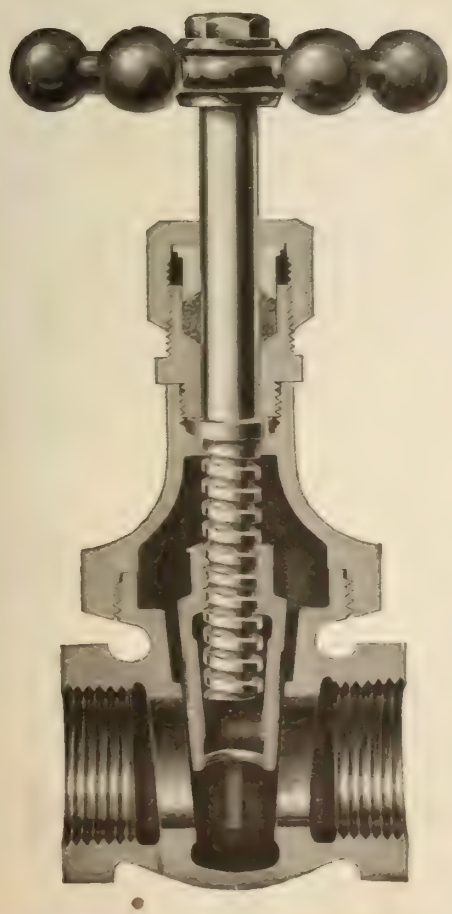
PENBERTHY

Brass Gate Valve



"THE ALL-QUALITY LINE"

PENBERTHY Brass Gate Valves embody the same excellent feature that characterizes "The All-Quality Line," viz: the EXTERNAL THREAD CONSTRUCTION. This is a feature that will appeal to all steam users. It permits quick accessibility to the valve at all times; and prevents straining or spreading of body, or stripping and corrosion of threads. It is simple, practical and safe.

All Penberthy Gate Valves are designed with the solid Disc wedge and non-rising spindle, and are registered and approved by all Provinces. They are manufactured of the best steam metal and are guaranteed to give the best of service under the most severe conditions.

Positive Oil delivery— in measured quantity.

LUNKENHEIMER CYLINDER LUBRICATORS

For Steam, Gas and Oil Engines, Pumps and Compressors,

are a material aid to efficiency in the production of power, safety in operation and economy in maintenance.

They deliver with precision the necessary quantity of oil for reducing frictional resistance to a minimum, effecting a saving of lubricant as well as insuring the service life of the equipment.

Fig. 1014—"Invincible" is mechanically operated and is made in one to four feeds with capacities from one quart to one gallon.

Fig. 482—"Senior" is a double connection hydrostatically operated lubricator made in capacities from ¼ pt. to 1 gal.

Fig. 486—"Junior," single connection, hydrostatically operated lubricator, made in capacities from ¼ to ½ pt.

Fig. 495—"Alpha" is hand operated and serves as an auxiliary to the Sight-feed lubricator to force a quantity of oil to the cylinder when starting or for emergency.

Booklets 518-DC and 526-DC contain authoritative data on Cylinder Lubrication and list all types of Lunkenheimer Lubricators. They are yours for the asking.

Service Considered—
Look for the Trade Mark
GENUINE OAK
It's Your Guarantee
It's in the Grip—Not Tension!
If your belts are slipping, tightening them won't help any. Extra tension, as you know, plays particular havoc with belting, besides straining the shaftings and wearing out bearings.
It's grip that's needed to keep Power House transmission costs down, and the gripping power of any leather belt depends entirely on the tanning process.
That's why D. K. McLaren's Belting hugs the pulley with a grip that can't slip—because it's all Oak-Tanned by the genuine British process. It's a long-time process and generally considered too expensive to use, but every foot of D. K. McLaren's Belting is made flexible and practically stretchless by this method—that Oak Leaf says so.

An economy when buying machines or supplies

Because the Canadian Fairbanks-Morse Co., Limited, is "Canada's Departmental House for Mechanical Goods"—selling everything your business needs in the highest-grade machinery and supplies—it offers you all the savings of grouped orders and bulk shipments.

And this economy of centralized purchasing brings with it an assurance of dependable quality and sound values because the Canadian Fairbanks-Morse catalog lists the products of the foremost manufacturers.

Furthermore, each department is under the supervision of experienced men who know how best to fulfill your exact requirements.

Make our nearest Branch your buying centre and our catalog your guide to the most reliable mechanical goods.

Keeps Heating Systems at high Temperature

C S C Steam Trap Systems drain steam lines of all condensation, resulting in reduced fuel costs and the maintaining of higher temperatures in heating systems.

By returning the condensation at a temperature of 212 degrees or higher, direct to boilers, without the aid of pumps, C S C Systems make possible a fuel saving of 15 per cent. or more.

If you have a heating problem—a building difficult to heat because of condensation in steam lines—you are assured that the C S C Trap System will keep that heating system at topmost efficiency. Write to-day for our booklet in which the C S C System is described in detail.

JENKINS BRASS GLOBE VALVE
Standard Pattern

Suitable for 150 pounds working steam pressure, 250 pounds working water pressure.

INSTALL JENKINS VALVES

They'll open easily and close tightly. They won't leak. They'll withstand severe service, rough usage and careless handling. They're made that way.

The dependability and longevity of Jenkins Valves are due to careful construction in every detail and to the Jenkins Valve Disc which prevents wearing metal to metal action between disc and seat.

Genuine Jenkins Valves are made of brass, iron and cast steel—types and sizes to meet every requirement. Like the genuine Jenkins Discs they are known by the Jenkins Diamond Trade Mark.

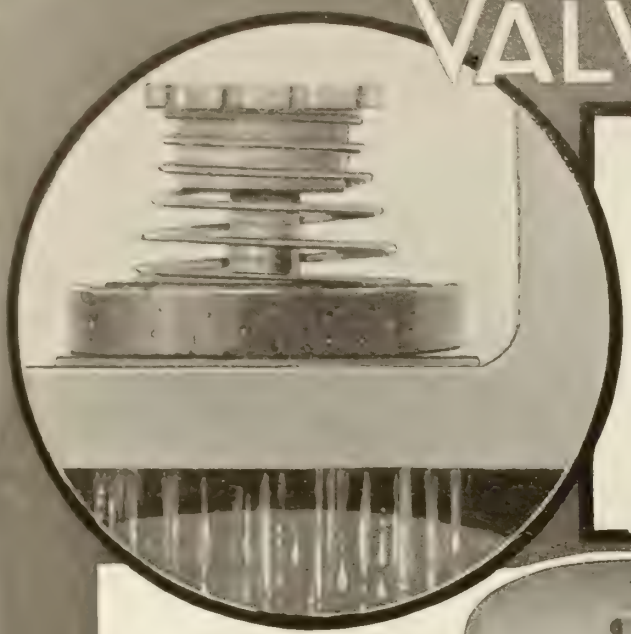
VALVE LEAKAGE



When slip due to valve leakage in the water end is added to thermal losses in the steam end the final efficiency of the average pump becomes very low.

To be successful, pump valves must be selected to suit the diversified requirements of pumping service.

Garlock Pump Valves are scientifically compounded and prepared for each special service.

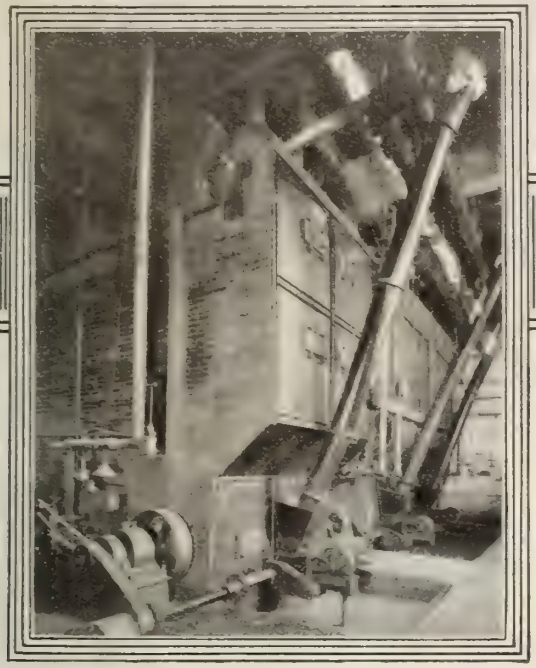
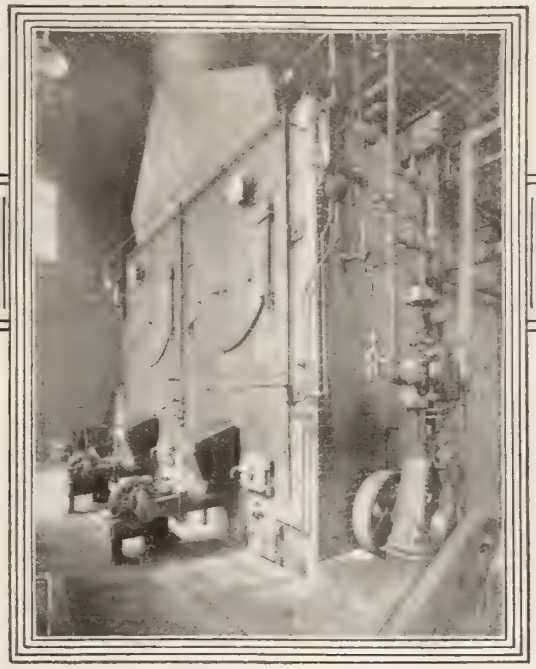
Detroit Single Retort Stokers Save Money





The Detroit Single Retort Underfeed Stoker has demonstrated in actual practice that its installation results in the following economies.

1. Fuel Saving: Saves ten to twenty per cent of coal—a result due to more nearly complete combustion. Hand fired plants average fifty to fifty-five per cent overall boiler efficiency, whereas Detroit Stoker fired boilers average seventy to seventy-five per cent and over.

2. Labor Saving: Saves approximately fifty per cent of boiler room labor, depending upon plant conditions.

3. Cheaper Coal: Burns lower grades of fuel than is possible with hand firing. Savings thus effected may be of such magnitude as to pay for the cost of the Stokers each year.

4. Increases Boiler Capacity: Detroit Stoker fired boilers may be continuously driven to much higher ratings than hand fired boilers. This assures an adequate supply of steam at all times. It may permit shutting down one or more boilers, or, where demands are heavy, obviate the necessity of buying additional boilers.

5. Smokeless Operation: With Detroit Stokers smokeless operation at all loads is secured through practically complete combustion.

6. Eliminates Human Factor: Man's efforts constantly vary in intensity and skill. A fireman doing first class work in the morning will be less attentive in the afternoon when he is tired. His efficiency moves up and down from hour to hour and from day to day. Presently he leaves the plant and a new man takes his place. Contrast this condition with one where Detroit Stokers are employed. Steady even production follows as a matter of course. Steam pressure remains constant—the same amount of coal produces the same amount of steam week in and week out—boiler efficiency is uniform.

7. Meets Emergencies: Suddenly varying loads on boilers of medium size, particularly where the number of steam generators in a plant is limited, offer a real firing problem. Hand firing, because of its slowness and the uncertainties of the human element, does not offer a satisfactory solution. Rapid production of steam to meet heavy requirements call for an Underfeed Stoker of the Detroit Single Retort type—a machine especially built for this service.

On every score your boilers should be equipped with Detroit Stokers. Remember, there is a type for every purpose—V-Type Overfeed for natural draft—Single Retort Underfeed for forced draft with boilers developing up to 300-400 H. P.—Multiple Retort Underfeed for large boilers.

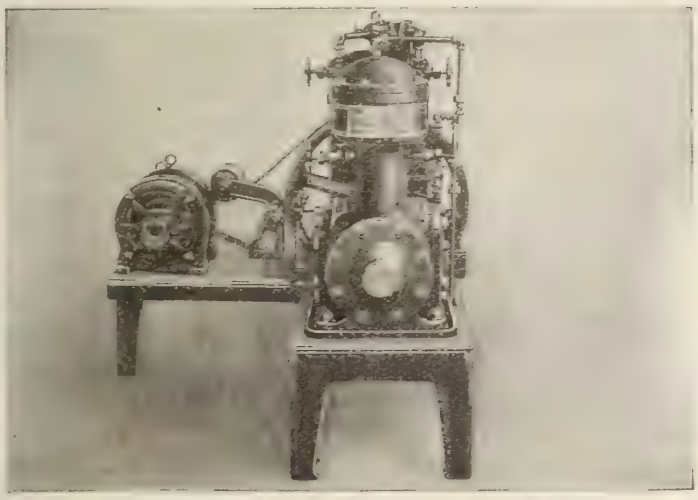
Ice Making and Refrigerating Machinery Exclusively



FRICK Combined Refrigerating Machine

This machine fills the needs of dairies, groceries, meat markets, restaurants, hospitals, confectionery and floral shops, etc., for a simple and efficient small refrigerating plant.

The machine is manufactured in one ton and two ton sizes. It is a complete self contained unit, including compressor, condenser, separator, receiver and connections mounted on one solid portable iron base as shown. It is completely assembled in one crate with motor and motor base in separate box, and can be taken through a 26 inch door without uncrating.

No foundation is required. The machine is as easily put in place as the ordinary counter or refrigerator, and as easily removed—an important feature to the user who rents his place of business.

Machine is completely protected with safety devices. Either part automatic or full automatic control is supplied as desired. It is unusually quiet in operation and can be placed in any desirable location.

Ask our nearest distributor for further details and prices.

Ask for a copy of our List of Users covering 48 pages of satisfied customers—also your copy of Ice and Frost.

Insulated with Nonpareil Corkboard—*one of the general storage rooms of the Commonwealth Ice & Cold Storage Company, South Boston, Mass.*

When You Insulate

When you insulate cold storage rooms you need reliable information on two points:

1. The kind of material that will be most efficient in retarding heat and most durable in service.
2. How to use it, i.e., thickness and method of erection, to insure maximum economy.

Results are what interest you, and results can be satisfactory only when the *best material* is *properly used.*

Nonpareil Corkboard Insulation

For all Cold Storage Rooms

represents the maximum value in cold storage insulation because it combines a competent advisory service with a commodity of established worth—Nonpareil Corkboard. It assures you not only of the most efficient and durable insulating material, but insulation that is correctly designed to meet your particular requirements economically.

Are you building or planning new rooms? Helpful information, literature and samples will be furnished on request. No obligation.

Armstrong Cork & Insulation Co., Ltd.

503 McGill Bldg. **Montreal, Que.**

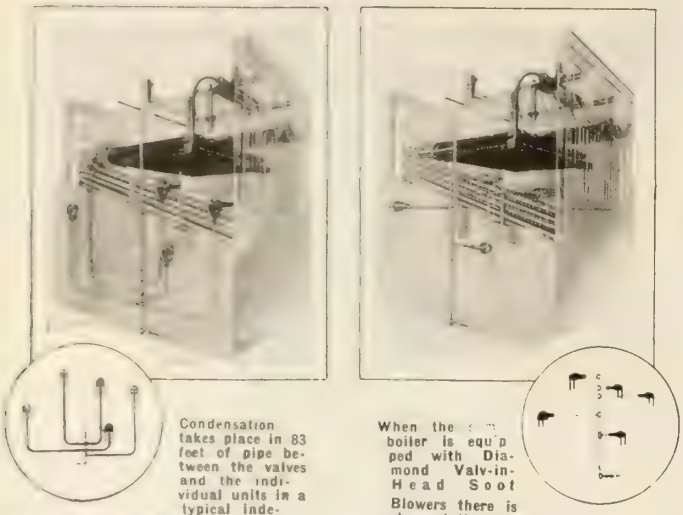
Diamond Valv-in-Head Soot Blowers Eliminate Condensate and Reduce Blower Maintenance



Condensation takes place in 83 feet of pipe between the valves and the individual units in a typical independent valve soot blower installation.

When the boiler is equipped with Diamond Valv-in-Head Soot Blowers there is beyond the valve no pipe whatever in which condensate may form and be carried over to the blower element.

The practical results of the elimination of condensate from the blower element achieved by Diamond Valv-in-Head construction are: increased length of service of boiler tubes; complete removal of soot with no caked deposits left behind; and long life of soot blower elements, with a reduction in annual blower maintenance charges from 25 to 50 per cent.

Elimination of condensate is only one of eleven important advantages of Diamond Valv-in-Head soot blowers. Others include a 50 per cent. saving in labor for operation, and a saving of 50 to 60 per cent. in steam. Remember that Diamond blower elements used in the hot passes of water tube boilers are CALORIZED.

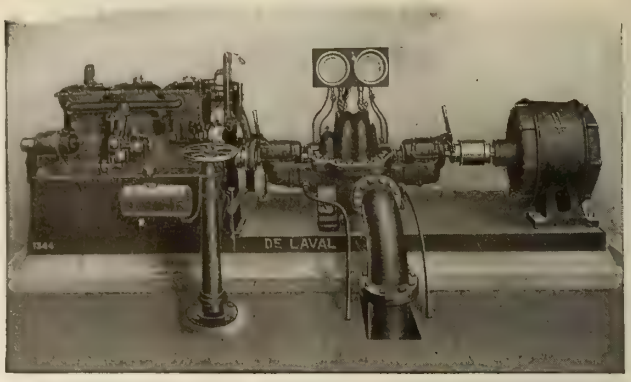
VALV-IN-HEAD SOOT BLOWERS



Reliable Water Supply At Low Cost

FOR DRIVING pumps of small and moderate sizes, particularly when placed in remote locations, electric power is often cheapest. Electric distribution systems, however, are subject to interruptions of service, as from storms, power house accidents, etc. A number of users of De Laval pumps, therefore, have insured continuity of service by installing gas or gasoline engines as "stand-bys."

The photograph shows a De Laval two-stage centrifugal pump driven by a Sterling gas engine, as installed at Lindsay, Ont. The pump is designed to deliver 1,325 gal. per min. against 290 ft. head, when running at 1,450 r.p.m.

De Laval centrifugal pumps have been specially designed to give regular, continuous service. All internal parts are accessible upon lifting the casing cover, and can then be lifted out after removing the bearing caps. Parts subject to wear, such as bearings, shaft sleeves, impellers, wearing rings, etc., are made to limit gages and are interchangeable. Repair parts can be obtained by giving the number which is stamped upon each part.

Their high efficiency and low starting torque are peculiarly valuable where electric power is used. All De Laval pumps are guaranteed as to efficiency, and the efficiency is demonstrated by test before the pump leaves the works.

YARWAY SEATLESS BLOW-OFF VALVES in the plant of the Public Service Electric Co., Perth Amboy, N. J.

YARWAY SEATLESS AND YARWAY DOUBLE-TIGHTENING VALVES in tandem arrangement. The ideal combination for blow-off lines where two valves are desired.

Just Valves, or BLOW-OFF *Valves?*

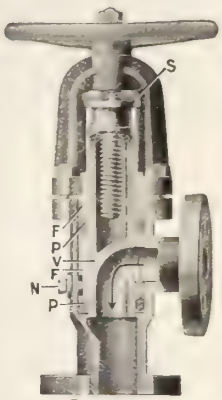
A LIMOUSINE makes an excellent passenger car, but it isn't much good as a truck. A freight car makes a poor Pullman.

It's the same with valves. A valve may give excellent service in one part of the boiler room, but move it somewhere else and it's worse than useless.

Except under very favorable conditions, an ordinary gate valve is totally unfitted for blow-off service. It wasn't made to withstand the destructive action of mud, grit and sediment under high pressure—and it can't. The seat soon becomes scored and worn, and this ordinary valve begins to leak away valuable fuel.

That's why it pays to equip your boiler with a plunger type valve—the YARWAY SEATLESS BLOW-OFF VALVE. It's built especially to stand up in blow-off service. It has no seat to leak; therefore it stays tight, keeps the water and steam where they belong, and saves fuel.

"The Solution of the Worst Boiler Room Problem" tells why this valve is best fitted for blow-off service, and also describes the YARWAY DOUBLE-TIGHTENING VALVE, frequently used in tandem with the Yarway Seatless. We'll gladly forward a copy at your request.



Operation

After valve has closed, shoulder S on plunger V engages the loose follower gland F. A hard turn of handwheel then compresses packing P above and below the port, making an absolutely tight valve. Set-screw N prevents turning of gland when handwheel is turned.

Packings for Two Services Both Equally Good

For
STEAM AND COMPRESSED AIR
there is no packing to equal

"PALMETTO"

because the materials of which it is made, as well as the lubricant carried in each single strand, give it a length of service that means real economy.

"Palmetto" is heat resisting, and does not harden in service. It is therefore especially adapted to high speed engines working under high pressure, superheated steam, the very place where most packings fall down.

For
HYDRAULIC PRESSURES
use

SQUARE
PALCO
PLAITED PACKING

made of high tensile strength cotton yarn, carrying a graphite grease lubricant in each single strand.
"Palco" will not swell and bind the piston as to cause the pump to short stroke.
The lubricant which "Palco" carries reduces friction to a minimum, and enhances the life of the packing.
"Palco" is superior to square flax packing.

Let us send you working samples of these packings to test under your own conditions. We make no charge for these samples, as we are anxious to convince you of their merit.

"SPRA-RITE"

Shows its Effect on the Coal Pile

Spra-Rite Cooling Systems have proved their efficiency. Tests made on the coal pile by means of the increased vacuum obtained prove that many systems have made a 50 to 100 per cent. return on the original investment in a year's time. Frequently a reduction in insurance rates is also obtained by reason of ample water supply close at hand for use by fire pumps. You should know more about SPRA-RITE —have us explain the system fully.

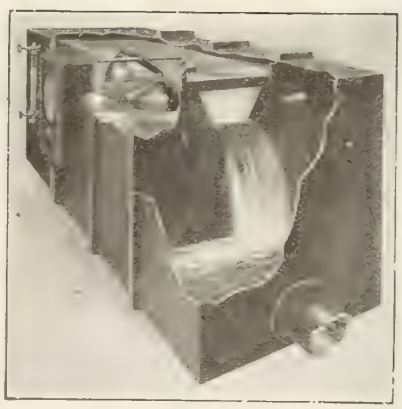
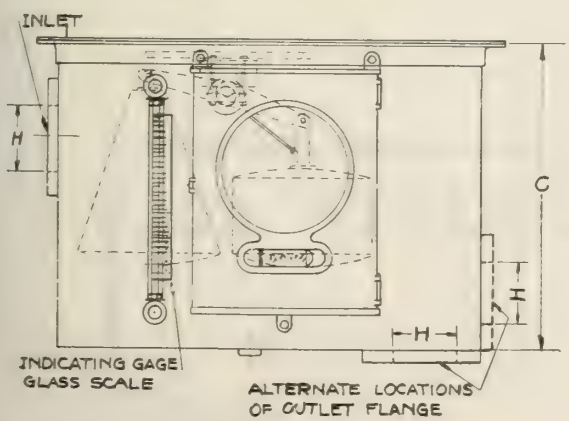
Bailey Weir Meter

Accuracy Where the Smallest Error is Serious

The design of the Bailey Weir Meter entirely obviates the possibility of error due to determining the true zero water level. The pen and integrator can be set to their true zero as long as the water level is within ½″ of the bottom of the notch, and there will be no error at the higher readings.





The Bailey indicates, records and integrates the flow of liquids. The pulsating effect of reciprocating pumps does not affect its accuracy. It is extremely simple in construction and is entirely free from troubles arising through the use of cams, springs, racks, gears and other intricate parts. The recorder and integrator are enclosed in a neat iron case and the charts may also show the water temperature.

Write for sizes and complete details.

CAST IRON OPEN TYPE FEED WATER HEATER

Is a combination Feed Water Heater, Purifier and Oil Extractor of the open or exhaust steam type. It effectively extracts oils and grease from exhaust steam and delivers the feed water at near boiling temperature, and also takes out any scale-forming matter that may be precipitated at this temperature. A feature of this feed water heater lies in its compactness. Up to 500 horsepower the casing is of the solid type as shown on the left. Above this size and up to 5,000 h.p. the casing is built in sections. See illustration on the right.

Complete information regarding these highly efficient heaters promptly furnished on request.

Combustion for the Boiler Room Operator

The Amount of Oxygen Necessary to Burn One Pound of Coal—How This Oxygen is Carried in With the Air—Draft, and Its Measurement in Inches of Water

By T. H. FENNER

BEFORE starting on a discussion of the processes of combustion, let us assure those who are not familiar with it, that there is nothing to be alarmed about. The chemist has come to the aid of the engineer in explaining certain natural laws in which the engineer is deeply interested, and has placed in his hands a simple means of determining the performance of the furnace which is the beginning of the process of generating power from steam.

We have seen that nature has combined a certain number of different organisms into a solid bulk, which we get back from the earth either as coal, or as a fluid oil. The storing up of these materials occupied many centuries, but they can be won back in much less time, and the heat stored up in them can be released very swiftly, if we go about it the right way. The one thing necessary in order to get the heat out of the fuel is that the carbon and hydrogen, which are the heat-containing constituents, shall be liberated and mixed with a sufficient supply of oxygen to enable them to give up their heat, and be changed into a different combination entirely.

Now this oxygen is around us in plentiful quantity, but unfortunately it does not exist as a separate commodity. It is in combination with another gas, and these two gases form the air we breathe. In order to get the oxygen, we have to use the air, with its content of nitrogen, which is of no use to us. Air is composed of pretty closely 21 parts of oxygen and 79 parts of nitrogen in every 100, and it is the 21 parts of oxygen that are of use to us in the process of combustion. So that we shall be able to get this oxygen to mix with our carbon, and thus get the heat we require, we must find a method of passing a certain amount of air through our fuel. To get the right amount, we must first of all find out what is this correct quantity, and then find a means of introducing it to the fuel in an efficient manner.

It is at this point that the chemist steps in and gives the engineer the needed assistance. He tells us accurately how much oxygen we require per lb. of carbon, and also how much air we must use to get this amount of oxygen. How we are to get the air he leaves to us, that being a strictly mechanical problem. Let us see then, how much oxygen we must use to burn to the utmost advantage a pound of fuel, with its different constituents.

The chemist compares the different elements by means of their "Atomic" weights. Thus the atomic weight of carbon is 12, and that of oxygen 16. Therefore, as the oxygen in the air combines with carbon during the process of combustion in the proportion of two of oxygen to one of carbon, forming what the chemist calls CO_2, or carbon dioxide, the proportion of oxygen to carbon will be as 12 is to 32. Then get for the weight of oxygen required the amount of carbon multiplied by 32 and divided by 12. Suppose the coal we are using contains 78 per cent. carbon, then

$$\text{we will require } \frac{.78 \times 32}{12} = 2.08 \text{ lbs}$$

oxygen for the carbon content.

The hydrogen in the coal combines with the oxygen to form water, the chemical symbol of which is H_2O. The proportion of the weight of H_2 to O is as 2 is to 16, or 1 to 8. Then if the hydrogen content of the coal is 6 per cent., we shall have as the oxygen necessary H x 8, and using the percentage we have .06 x 8 = .48 lbs. oxygen.

The coal itself we shall say contains 5 per cent. oxygen, and therefore this amount will have to be deducted from the amount of oxygen to be supplied. We have then 2.08 lbs. oxygen for the carbon, and .48 lbs. for the hydrogen which gives 2.56 lbs. Deducting .05 for oxygen contained in the coal we get 2.51 lbs. oxygen required for the one lb. of coal.

Now we have said that the air contains 21 per cent. oxygen and 79 per cent. nitrogen. We shall therefore have only 21 per cent. of oxygen in each lb. of air, so to obtain one lb. of oxygen we shall require 100/21 lbs. air. Then we shall need for our one lb. of fuel

$$\frac{2.51 \times 100}{21} = \frac{251}{21} = 11.9 \text{ lbs air.}$$

We might say 12 lbs. air are required for one lb. of coal. The amount of air required per pound of coal will naturally fluctuate with the chemical constituents of the coal, but this is taken as the theoretical amount of air that is required.

We shall find that in actual practice we must have more than this amount, but that the closer we can keep the air used to the theoretical amount, the better results we shall get. This will be demonstrated later.

Procuring the Air

We have thus far noted the constituents of the fuel that we use, and its heat value. We have also seen that in order to obtain the heat we must supply a certain amount of air. That brings us naturally to the means of supplying the air in the proper quantity, and the first thing we have to consider in this respect is "draft."

What we call draft is a difference of pressure between the air in one part of a structure and another part, which causes a flow of air from the high pressure region to the low pressure. The difference is usually but a slight one, and may be created by either natural or artificial causes. The best examples of natural draft that we have are the winds, which vary in magnitude and direction from day to day and hour to hour in some places and in others blow steadily in one direction for a considerable length of time and then reverse the direction, and blow just as steadily for a corresponding length of time. These latter winds are known as "trade winds" or "monsoons." Without going into any prolonged explanation, we may say that these winds are caused by a long season of hot weather, which causes a lessening of the density of the air over a large area, with a corresponding lowering of pressure. In order to equalize this the air moves from a region of higher pressure, and thus maintains a steady air current until the gap is filled.

We have exactly the same thing occurring in the furnace and chimney of a boiler. As soon as a fire is lighted in the furnace, the air is heated, and expands. This naturally lowers its density, or pressure, and an inequality of pressure is established between the furnace and the outside air, the air in the furnace being at less than atmospheric pressure. The result is that the outside air pours in, trying to restore the balance. In so doing, a fresh supply of air is given to the fuel, and combustion continues, constantly heating the air, while the outside air is constantly trying to maintain equilibrium, and thus we have the familiar phenomenon o draft.

This is of course just a general explanation. We must know a little more of the subject to understand it intelligently. Fortunately, we can do this without going into any very complicated figures, although we must use some of them. The density of the air varies with its absolute temperature, in a definite ratio which has been determined by scientists to be 1/492 increase of volume for every one degree of temperature added, on the Fahrenheit scale. If the Centrigrade scale is used, there is an increase of 1273 volume for each degree added.

Now we see that the density varies with the absolute temperature, but we want some means of finding just how it varies. We therefore take the absolute temperature of air at freezing point Fahrenheit, which is 32 plus 460, or 492 as a standard. By dividing the absolute temperature at any other point on the scale into this figure, and multiplying the result by a factor for the specific heat, we get the density. Thus suppose we have air at 60 degrees, then the density at that temperature will be

$$\frac{460 + 32}{460 + 60} \times .0807 = .076$$

which works out to .076.

Suppose the air in the chimney were at 600 degrees then its absolute temperature would be 1.060. Dividing this into 492 and multiplying by .084 which is the factor at this temperature we get .038.

These factors for specific heat have been determined by experiment, and we just accept them as being correct. They will vary slightly, but the temperatures for atmospheric air and chimney gases are so nearly constant that these factors can be used in practically all cases.

We usually measure the force of draft in inches of water, and this is arrived at in this way. The pressure of the atmosphere is 14.7 lbs. per square inch, and this pressure is sufficient to balance a column of water 33.8 feet high. Then each pound pressure is equal to a height

$$\frac{33.86}{14.7} = 2.304$$

Then we have from this the fact that a column of water 2.304 feet high will give a pressure of one lb. per square inch on its base, and that the pressure per square inch is equal to the height x .434. Now for convenience we can reduce these terms to inches and ounces.

2.304 feet x 12=27.648 inches. Dividing this by 16, the number of ounces in 1 lb., we have

$$\frac{27.648}{16} = 1.728 \text{ inches}$$

That is 1.728 inches equal 1 ounce pressure, or 1 inch water column is equal to .57 ounces pressure. It is fairly safe to reckon ½ ounce of pressure per one inch water column in ordinary boiler-room work.

We can now bring into use a formula derived by Professor Rankine, to whom the engineering world owes quite a debt. This formula will give us the force of draught for any height and any difference in density of the gases. Let F equal the force in inches of water
D equal the density of atmosphere
d equal the density of flue gas
h equal the height of the chimney
Then F=.192h (D—d)

The factor .192 is used to convert pressure per square foot into inches of water. One ounce per square inch is equal to 144 ounces per square foot, and the height of water column corresponding to this pressure is 1.728 inches. As density is always reckoned in pounds per cubic foot, then the head or pressure must be reckoned in pounds per square foot, so instead of 144 ounces we say 9 lbs. per square foot. If we divide this 9 into the height of the water column we get the height of water column for a pressure of 1 lb. per square foot, which is .192.

To apply the formula, let us suppose that we have a chimney 150 feet high, and that the temperature of the atmosphere in the boiler room is 70 degrees, while the flue gases are leaving the boiler at 650 degrees. We wish to ascertain the force of the draught. First we must find the density of the two different gases. First the atmosphere, which will be

$$\frac{460+32}{460+70} \times .0807 = .074$$

Then the flue gases,

$$\frac{460 \times 32}{460+650} \times .084 = .037$$

We can now apply the formula

$$F = .192h\ (D-d) = .192 \times 150\ (.074—.037) = 28.8 \times .037 = 1.0656$$

That is the draught would be equal to a column of water just over 1 inch high, corresponding to a pressure of .57 ounces.

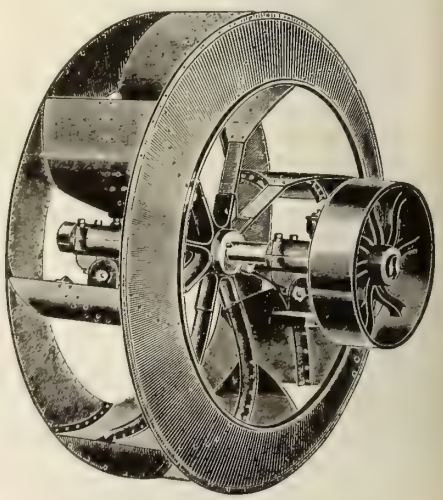
We thus see that with the ordinary chimney draft the intensity of the draft, or in other words, the difference of pressure, depends on the difference in temperature, and the height of the stack.

When we use a fan for draft, we create the difference of pressure by mechanical means, by drawing in air at atmospheric pressure on the suction side of the fan, and compressing it, discharging it into the ashpit or tuyeres of the furnace under higher than atmospheric pressure. The air above the fire being at atmospheric pressure or slightly below it, we have thus a considerable difference of pressure above that which can be obtained by natural draft, and we further have an apparatus which can be regulated to give any desired difference within reason. As the chimney is not required to assist in producing draft, a much shorter stack can be used, thus reducing the cost of this part of the construction.

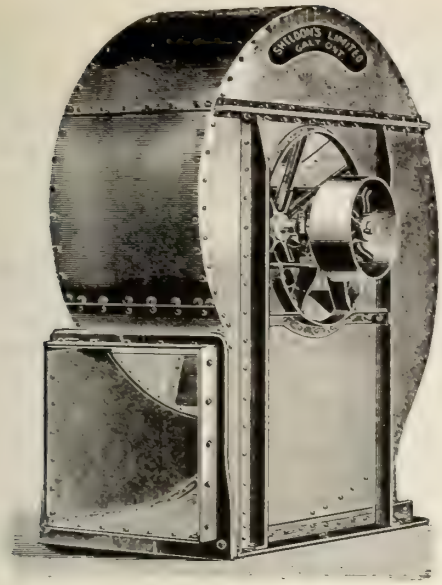
There is a third method of producing draft, known as induced draft. In this method either a fan or a special form of stack is used, but instead of the fan being used to create a pressure in the ashpit it is used to reduce the pressure in the setting and breeching. The fan is set in the uptake of the boiler, and draws the gases from the breeching and discharges them into the atmosphere, through a short stack. Owing to the much greater volume of the hot gases, the fan must be of much larger size than the forced draft fan, and provision must be made for by-passing the gases around the fan and to the stack direct, at such times as the fan may not be working.

With the special form of smoke stack, known as the Evase method, the stack is formed with a tapering throat of the Venturi type, and an air jet is blown through this in the same manner as steam is blown through the orifice of an injector, and with the same result.

Whichever method is used, the object is the same, and that is to get sufficient oxygen to mix with the carbon to complete combustion. The amount of air required will of course vary with the amount of fuel which is being burned per hour, and therefore it is very necessary that some means of regulation should be adopted. In the case of the natural draft produced by a chimney, the regulation is performed by means of a damper in the stack, which closes off a portion of the area, or can be made to completely close it if necessary. Ashpit dampers are also

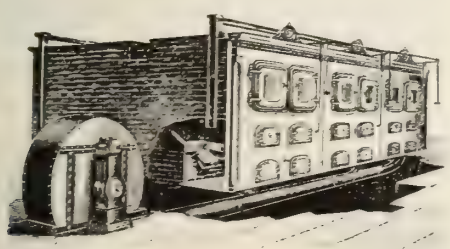


Steel Fan Wheel.



Complete Fan and Casing.

provided, which check the air going into the ashpit, but these dampers would be much better left off altogether. The proper way to check the draft in a natural draught furnace is by the chimney damper. This effectually cuts off the draft, and at the same time tends to equalize the pressure between the furnace and the outside air, thus preventing any infiltration of cold air through the brick work. On the other hand, when the ashpit dampers are closed and the chimney damper left open, the resulting difference of pressure is much greater than normal, and air is drawn in through every crack and crevice of the brickwork, cooling down all the heating surfaces. Another thing that can happen through injudicious use of the dampers is a gas explosion, to the undoing of the brickwork or a portion of it. If the chimney is pretty nearly closed off, and the ashpit dampers are also closed, the process of combustion is halted, and the gases in the furnace become instead of carbon di-oxide, which they should be, only carbon monoxide. This means that the furnace has practically become a gas producer, and the chimney damper being



Forced Draft Arrangement.

nearly closed, the gas does not get away. Pretty soon the steam goes down, and the fireman opens up ashpit and chimney dampers. The result is that the admission of this air to the partially consumed fuel, gives such a quantity of oxygen that the resulting completion of combustion occurs at such a rapid rate that it really becomes explosive in its force. The area of the chimney is not enough to carry away the suddenly increased volume of gas and the result is that the back wall or side walls, are blown out, and everyone wonders what has happened.

This thing occurs very frequently on boilers fired with sawdust and wood refuse, and can happen with either natural or forced draft, and does happen even in plants where such a thing would not be expected.

(To be continued)

LOSSES DUE TO TOO MUCH CARBON MONOXIDE?

By W. F. Schaphorst

This chart gives the fuel loss due to too much carbon monoxide in the flue gases. To determine the loss no figuring is necessary. Just zigzag a straightedge across the chart three times as indicated by the dotted lines and column G immediately gives the per cent. of fuel loss.

For example, a given coal contains 70 per cent. of carbon; the fuel gas contains 10% carbon dioxide (CO^2) and 1% carbon monoxide (CO); the heat value of the coal is 12,000 B. t. u. per pound. What is the fuel loss?

Run a line through the 70 (column A) and the sum of CO^2 plus CO (column B) and locate the intersection with column C. From that located point run through the 1 (Column D) and locate the intersection in column E. From that point run through the 12,000 (column F) and the intersection with column G shows the answer—5.4 per cent. The operation is the height of simplicity for the line is carried directly across from left to right; there is nothing confusing about it.

The range of the chart is wide enough to take care of nearly every condition of flue gases. Should the intersection with column C or E fall "outside of the chart" it will make no difference. Merely extend the line C or E, whichever it may happen to be, and go ahead with the problem.

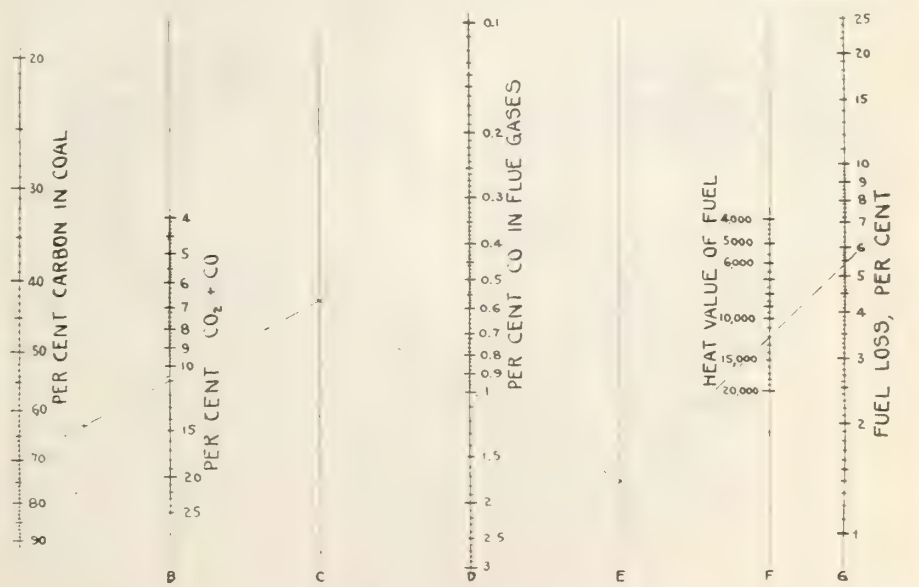
A little study given to the chart, coupled with a few examples of your own making, will soon show why the percentage of CO should be as low as possible and why the CO^2 should be high.

If it is desired to compute the percentage of fuel loss without using the chart it may be done in this way: Divide the percentage of carbon in the coal by the percentage of CO^2 plus CO; multiply by the percentage of CO; divide by the heat value of the coal per pound; and multiply by 10,150. The answer will be the same as given by the chart. The chart, of course, is much quicker.

ELECTRICAL BOILER

The Chicago Tribune, owns a paper mill at Thorold, and recently issued the following statement relative adoption of electricity for steam purposes:

"Arrangements have been completed to make steam in the 5,000 horsepower boilers of The Chicago Tribune's paper mill at Thorold by electricity. Motors in the mill are already operated from this source. Only steam for cooking sulphite and drying of paper on machines has been made from coal. The cost of the change over is less than $10,000, and can be completed in a fortnight. Already the mills of the Laurentide Paper Company, the Belgo-Canadian Paper Company, and the new mill of the International Paper Company, all located on the St. Maurice River near Quebec, have adopted electric furnaces. Electrical fuel competes with coal in making steam, according to the cost of two commodities at the point of use. It takes approximately one horsepower of electricity per year to furnish the heat given by one ton of good Pennsylvania bituminous coal."



Fuel Loss Chart.

Principles of Design of Air Compressors

The Influence of Different Types of Valves—Relation of Clearance Volume to Cylinder Volume—The Question of Efficient Cooling—Single and Multiple Stage Compression

By WILLIAM REAVELL
Before The Institute of Mechanical Engineers.

THE title of this paper obviously covers a very wide field, for any machine which aspires air—at whatever absolute pressure—and compresses it, would be comprised in such a title. Hence, a vacuum pump is an air-compressor, aspiring rarefied air which it compresses subsequently and delivers to the atmosphere. The title consequently covers all vacuum pumps and exhausters; and includes blowers, which are designed to elevate the air to slightly superior pressure, while, on the other hand, it embraces machines having several stages or cylinders, which ultimately deliver the air at extremely high pressure.

A machine which has to raise the pressure of air can be of the reciprocating piston type, or of the rotary type, including turbo-compressors, which Professor Rateau described in a paper at the Civil Engineering Congress in London in 1907, and which have been made in increasing numbers and sizes since then. At that congress the author dealt with reciprocating air compressors in a paper setting out those features necessary to ensure high efficiency in such machines.

In the present paper the author proposes to cover a wider field, and to deal with the features of different types of compressors which are required in each case to ensure that the most efficient results are secured.

The ordinary compressor or vacuum pump for normal use consists of a cylinder and piston actuated by a crank and connecting rod or other forms of mechanism, and containing inlet and outlet valves for the admission and egress of air.

Figs. 1 and 2 show such a cylinder of the double-acting type, Fig. 1 being fitted with "mushroom"-type suction valves and "thimble"-type delivery valves, and Fig. 2 having plate valves. Fig. 1 gives the lesser clearance, but Fig. 2 the better cooling.

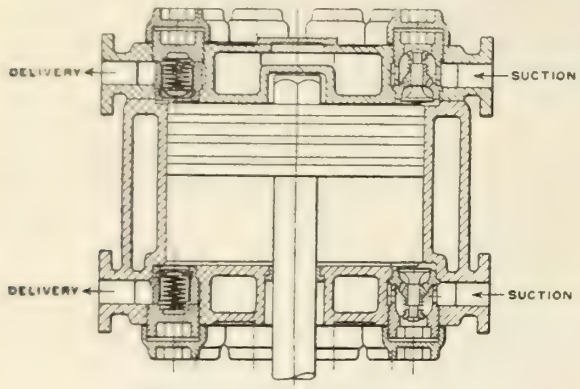


Fig. 1.

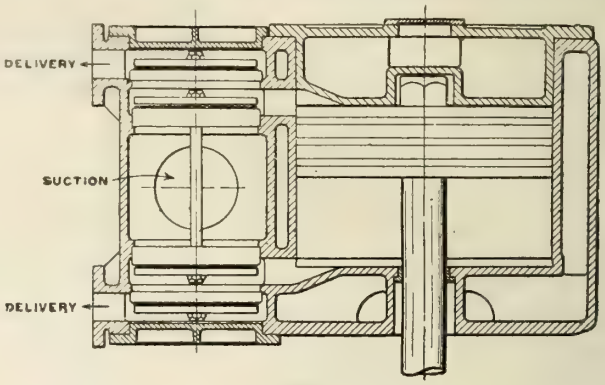

Fig. 2.

A careful designer would have before him the following considerations: (a) Clearance; (b) type of valve selected; (c) provision for cooling; and (d) form of piston-ring.

(a) Clearance.—The relation which the clearance volume bears to the cylinder volume, together with freedom from leakage in the piston-rings, is, neglecting temperature and valve resistance, the two factors which determine the ratio of the volume of free air delivered to the volume swept by the piston. The clearance volume is affected not only by the allowance made between the end of the cylinder and the piston, but by the space required for the valve pockets. The reduction of clearance to a minimum is not essential from the point of view of obtaining the lowest horse-power per cubic foot (or metre) of air delivered where the machines are fitted with automatic — that is, spring-loaded—inlet valves. A designer might elect, for other reasons, to have a larger amount of clearance than the minimum possible, but this is done at the expense of increasing the diameter of the cylinder; the greater the clearance, the longer will be the return travel of the piston on the suction stroke before the air which in the previous stroke has been compressed into that clearance has expanded back again to just below atmospheric pressure to allow the suction valves to open. Obviously, therefore, with an increased diameter of

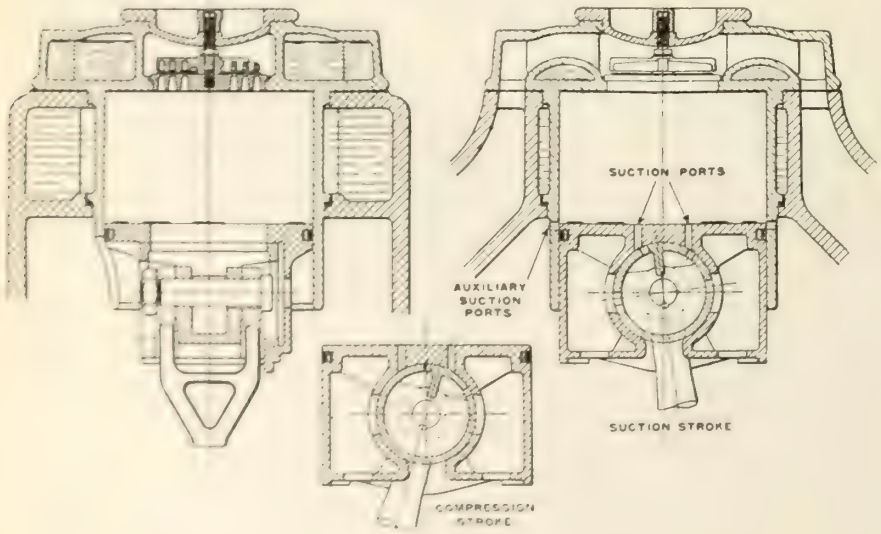

Fig. 3.

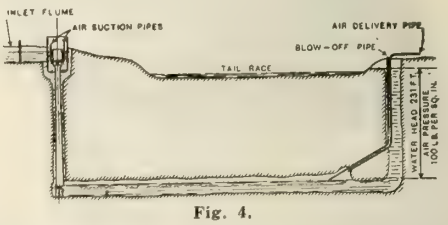

Fig. 4.

cylinder, the same volume can be drawn into the large cylinder as would be obtained in the smaller-cylinder with the minimum clearance.

With all spring-loaded suction valves there must be a slight reduction in the absolute pressure of air aspired, due to the fact that the atmospheric pressure has to overcome the resistance of the spring on the suction valve; consequently, in machines fitted with positively operated suction valves—for example, a piston-valve—or with ports in the piston and gudgeon or "top end" of the connecting-rod (as in the author's quadruplex compressor, a cylinder of which is shown in Fig. 3, the maximum ratio of volume of delivered air compared with the volume swept by the piston can be obtained.

free to open and close over the openings in the cover of the cylinder. The spring of the material was relied upon for the closing of the valve, but a guard-plate was fitted to limit the lift of the reeds.

The Rogler-Hoerbiger plate valve has a multiple-ported plate, which itself is provided with a flexible centre. In this construction the centre to the flexible plate is fixed, thus definitely guiding the plate valve and providing a spring action, although this spring is reinforced with supplementary spiral springs, suitably seated in a guard. In some cases a thin-steel cushion plate is inserted between the plate valve and the guard. In another form of Rogler valve, the valve itself is as described above, but instead of separate spiral springs, the spring valve

driving the machine is reduced to a minimum. Perhaps the only method of air compression which is used to-day in which isothermal compression is obtained is the hydraulic system used at Cobalt, Ontario, and similar installations, where a high vertical fall of water is used to perform the compressing operations. For those not familiar with this arrangement it might be described as follows:—

The water impounded at the top of the fall passes down a vertical pipe, and at the bottom flows into a chamber having a roof higher than the outlet of the pipe. Imprisoned air carried down by the water column is liberated in the underground chamber, and its pressure becomes that due to the head of water in the pipe.

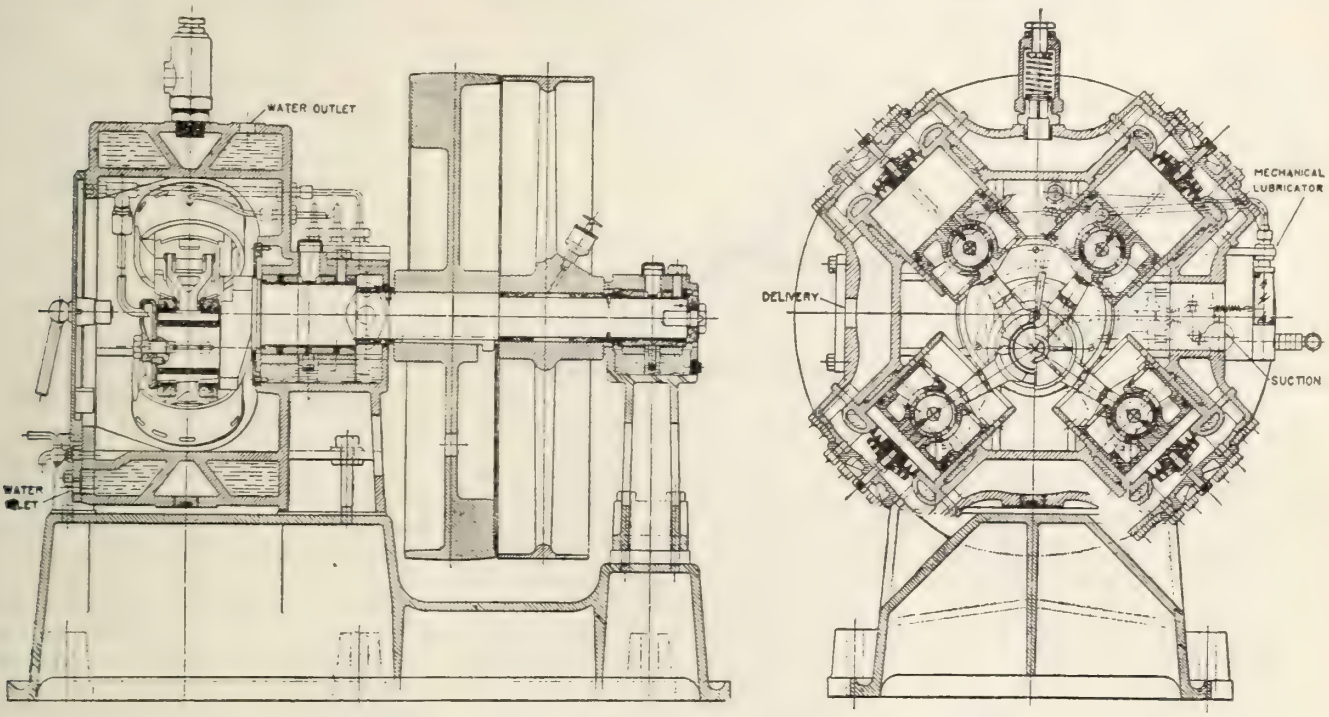

Fig. 5.

(b) Types of Valves.—In recent years the use of plate valves of various forms has become common. In their design and in the choice of materials used, it is important to provide that the construction and lift shall be such that the valves will not crack or break on the one hand, and on the other that they will not deform so as to cause leakage of pressure air during operation.

An early form of plate valve was that introduced by Mr. Mathewson in 1895, in which a disc-plate was controlled by a form of curved flat spring, as commonly used in electric-bell pushes, but having three points at equal distance apart, giving three-point pressure on the plate valve. This was one of the earliest types to avoid the use of separate coil springs.

Valves of the reed type, as used in motor-horns, were made at or before this date by Mr. Peter Brotherhood, a common arrangement being to arrange several reeds in a form of a star, the inner ends of the reeds being secured at the centre, and the projecting ends being

plate itself is reinforced by a strong stop plate, having four curved spring arms, giving four points where the spring pressure is applied to the outer rim of the plate valve.

In the Simplate valve a series of concentric thin annular plates, each separately guided by the cover plate are used, each concentric ring being controlled by small spiral springs seated in the cover plate.

Feather valve: This type of plate valve consists of a series of ribbon-steel strips of differing lengths, so as to seat in a circular plate having slotted ports to correspond with the length and width of each ribbon-steel valve. For this construction a valve guard confines the ends of each ribbon plate, but the plate is free to lift in the middle to allow the air to pass in or out. The ends of each ribbon plate are free to slide, and no additional springs are used.

(c) Cooling.—The problem of efficiently cooling a compressor cylinder and head is one which is extremely important, so as to ensure that the power absorbed in

(Fig. 4 shows this diagrammatically). An air-pipe carried through the roof of the underground chamber enables the air to be led away to the surface for use, and the tail-water rises to the lower surface level indicated and flows away.

In mechanically operated compressors, while isothermal compression is the ideal to be aimed at, it cannot be attained. It is well known that the difference between isothermal and adiabatic compression is represented by the indices to the volume in the following formulae:—

Isothermal compression $Pv=C$.

Adiabatic compression $Pv^{1.41}=C$.

It is clear, therefore, that the closer the index of compression approximates to the isothermal, the more efficient will be the machine.

In compressors of the single-stage type, any reduction from adiabatic compression can only be obtained by the abstraction of heat through the cylinder walls and head, except in special cases where water is injected into a cylinder and subsequently drained away from the discharged air. Consequently, the amount

of heat which can be abstracted depends :—

1. The diameter of the cylinder.
2. Piston speed (in other words, the "time" element).
3. Whether the construction is single or double acting.
4. The thickness of the cylinder walls and head.
5. The amount of the cylinder-head area which can be cooled.

A construction which would be rejected in steam-engine practice—because of the condensation which would be obtained—would, other things being equal, be an ideal contruction for an air compressor, from the point of view of efficient cooling. In large double-acting compressors, with a high piston speed and the thick cylinder walls demanded, very little reduction from adiabatic compression can be obtained.

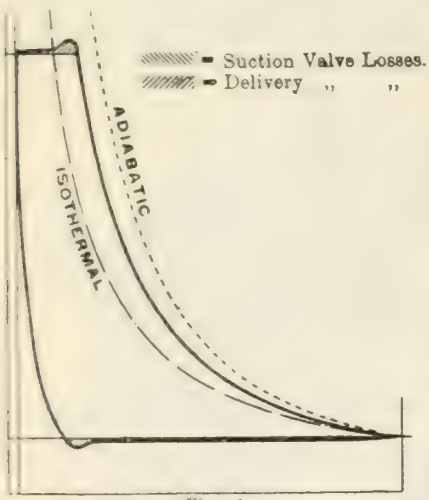

Fig. 6.

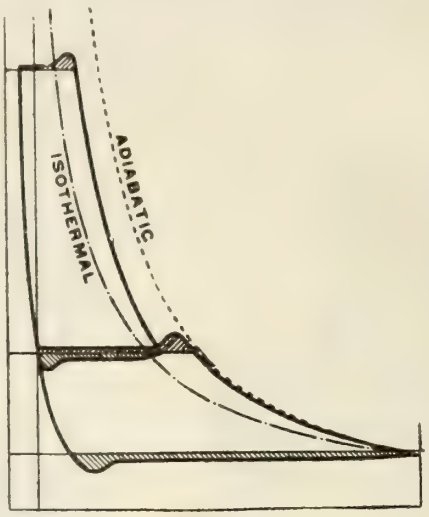

Fig. 7.

In compressors of the single-acting variety, having one idle stroke per revolution, so far as work done upon the air is concerned, the cooling will be better in multi-cylinder machines than in single-cylinder machines of the same total capacity. Where thin inserted liners are used for cylinders, the metal can be thinner than with a cylinder cast integrally with its jacket and flanges; hence, in the author's quadruplex compressor, Fig. 5, where four single-acting cylinders with thin walls are separately attached to a circumferential casing containing the crankshaft, and where moderate piston speeds are used, the cooling effect is probably the maximum obtainable in modern single-stage machines for 80 lb. to 100 lb. delivery pressure, and the index of compression is of the order of 1.23, or nearly half way between isothermal and adiabatic compression.

When compressing air in stages to higher pressures, this question of cooling has a definite bearing on the degree of compression which can be economically obtained while still retaining the simplicity of single-stage compression. In considering a two-stage compressor the author would point out that adiabatic [illegible] double-acting machines entails using two-stage cylinders for pressures for which that construction is not necessary when the cooling conditions are more ideal.

Fig. 6 shows a typical indicator card from a single-acting machine, the compression curve being constructed to the formula: $P v^{1.23} = C$. Superimposed on it are dotted curves, assuming isothermal and adiabatic compression.

Fig. 7 shows compression carried out to the same delivery pressure in two stages in a double-acting machine, the air, after the first stage of compression, being cooled in an intercooler almost to the initial temperature, and thereby reduced in volume; the compression curve (in both the first and second stage) is assumed as $P v^{1.35}$, as found in practice for high-speed machines of that type. The total area of the diagram is further increased by the fact that the delivery pressure in the first stage is higher than the intercooled pressure; and the suction pressure in the second stage lower than the intercooler pressure—by the resistance of the springs of the valves.

The results show that the total area of the single-stage machine (in full lines, Fig. 6) is less than the combined area of the two-stage diagram, Fig. 7, for the delivery pressure of 100lb. for which the diagrams are made. The closer the diagram Fig. 6 approaches to the isothermal the higher is the permissible delivery pressure for which single-stage compression is justified. Hence, in the single-acting quadruplex compressor, single-stage compression can be used for higher delivery pressures than in double-acting machines of higher piston speed.

Fig. 8 is a graph which shows the actual performance of single-stage machines, and indicates that of two-stage machines of similar capacity deduced from the above data. The pressures at which the curves cross one another will be noted.

(d) Piston-rings.—The airtightness of piston-rings has an obvious bearing on the volumetric efficiency obtained, and also on the horse-power per cubic foot or metre of air delivered. Leakage past the piston-rings being a function of time, tightness of piston-rings is of less relative importance with high piston speeds than with slower speeds, and in multi-stage machines piston-ring leakage, which tends to increase as the pressures become higher in succeeding stages, has the effect of increasing the pressure at the lower stage. Experiments by the author's firm indicate that better results are obtained if piston-rings, accurately machined to the cylinder diameter, can rely for their spring pressure upon a spring ring behind the packing ring (preferably with air packing), than if sprung-over rings of the Ramsbottom type are used.

These experiments also show that, in high-pressure pistons of three-stage machines, when several sets of rings were used, each set of piston-ring and spring ring should be carried in an independent carrier, the whole group being so secured by the junk ring that, while the series of carriers are firmly held, each set of rings has the requisite freedom of movement.

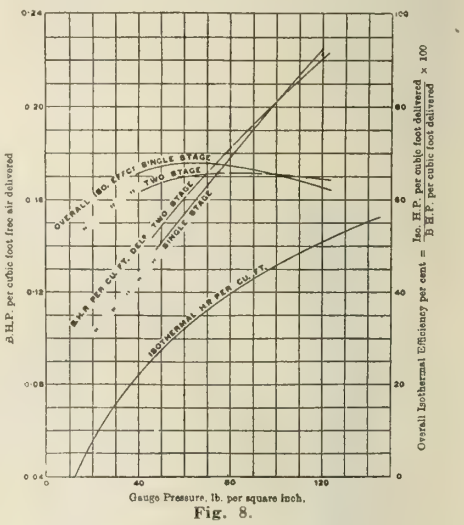

Fig. 8.

Multi-stage Compressors.—The same principles which govern the delivery pressure at which two-stage compression is adopted, apply also to compressors of more than two stages. When extreme pressures are used, the system of packing for the higher stages requires careful consideration. Modern British practice for pressures of 2,000lb. and above usually provides for fibre or similar packing for the final plunger in the form of neck-rings, the plunger or piston itself being without packing rings, and accurately guided.

A notable instance of design for extreme pressures was given in the discussion on a paper by Mr. West at a joint meeting in London of the Institution of Mechanical Engineers and the Society of Chemical Industry, where the super-compressor designed and made by the eminent French scientist, Professor Claude, of Paris, for 1,000 atmospheres pressure, in connection with his synthetic-ammonia process, was described. In the final stage of this machine the ground piston is packed with a hat leather, and cool working is ensured by making the plunger hollow, and supplying it with cooling water—an interesting solution of a difficult problem.

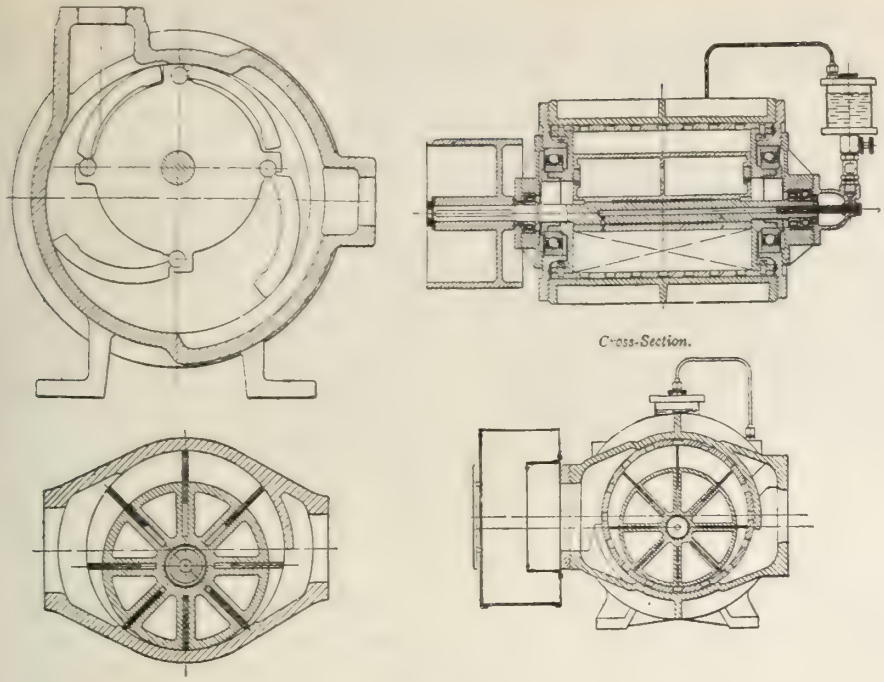

Fig. 9.

In multi-stage machines the practice in the construction of intercoolers has undergone a change, and the copper-coil coolers which were almost universal (and are still used in smaller machines of that type) are being replaced in large industrial compressors by straight-tube intercoolers. Copper coils, however, are still used in the final stages of such machines.

Straight-tube intercoolers should preferably be constructed on the "counter-current" principle, and with the air passing through the tubes while the water surrounds them. Provision must be made for blowing-off the water separated from the compressed air during cooling, and to provide that the air which may be separated out from the cooling water itself cannot form air pockets which might

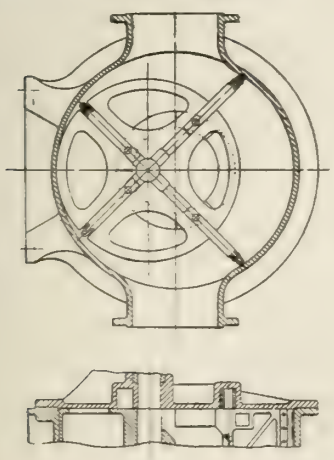

Fig. 10.

impede the free passage of the cooling water.

Rotary Compressors.—Just as, since the days of the Hero engine, the rotary principle has exercised a fascination for inventors, and has led up to the highly efficient steam turbine of to-day, so have succeeding generations of compressor designers endeavoured to apply this principle. Amongst the many forms experimented with, the crescent type is probably the most frequently used. In principle it consists of a rotor, the shaft of which is carried in bearings eccentric with the stator or casing, so that the path of any blade attached to the rotor sweeps a crescent form between the rotor and stator as the rotor revolves. One familiar type uses hinged blades, as in Fig. 9. Another uses sliding blades, as in Fig. 10. In some cases the blade is guided by curved slippers working in a turned groove in each end-cover, as in Fig. 11. This groove is concentric with the stator or casing; the slipper carries a pin attached to the blade, and hence the blade is suitably guided as the rotor rotates, so that the tip of the blade maintains approximate contact with the inside of the stator.

PACKING TROUBLES

By W. F. Schaphorst

In talking to a chief engineer not long ago I showed him a picture of a metallic packing which is giving very good service all over the United States and Canada. A point in its favor is that it need not be removed very often, if at all. An installation was inspected lately, for example, where a plunger equipped with this packing had been in operation for six years, operating against 160 pounds pressure, 212 degrees water, operating 12 hours per day, and the plunger was not so much as worn 1-1000 inch. The packing was still in perfect condition, and looked as though it should last 12 years more. The engineer in charge thought that the packing had saved him considerable time and labor and the owner considerable money. The chief engineer to whom I was talking, however, had his mind already made up, and was not open to conviction. He said, "I have tried metallic packing and will never try it again. It becomes a solid metallic mass, and if used in places that are difficult of access, it cannot be removed easily enough. I have had to chip it out in several instances."

It is regrettable that such chiefs still exist. This man is in charge of a large plant, and his mind should be open to new things. Improvements or attempts at improvements should be looked upon in an unbiased way, regardless of what experience may have taught with other equipment made of the same material. If all engineers had thrown up their hands after the first failure we would not have progressed very far in the manufacturing world by this time. With any packing, whether it be fabric or metallic, there are some cases where inaccessibility in design of stuffing boxes makes the packing very hard to remove. And the engineer's statement with reference to the metallic packing is true to the extent that it is more difficult to remove than the fabric, but it is the claim of this manufacturer that his packing needn't be removed. In other words, if the word of the manufacturer is reliable, as I hope it is, you can leave it in, and removal troubles are eliminated. In case it is necessary to remove certain metallic packings spirally it is not very difficult to screw into the packing itself with packing hooks made for the purpose, and pull the packing out. With separate individual rings, which do not amalgamate with the other rings the removal operation is performed with still greater ease.

So, all in all, the writer is convinced that the above chief engineer is considerably in the wrong. His case is analogous to the engineer who declared he would never install another centrifugal pump because he tried one once, and it wouldn't pump enough water. The pump he had was all right for its capacity, but what the engineer needed was a larger capacity pump. However, the engineer could not see it that way because he had been prejudiced against new fangled equipment from the start, and was determined to go back to the old form reciprocating pump, which was a steam waster, but he could speed it up when he wanted to pump greater volume of water in a given time.

FLEXIBLE PIPE HANGER

Messrs. W. H. Cunningham & Hill, Ltd., Richmond St., W., Toronto, are now putting on the market a flexible pipe hanger. This galvanized band can be easily bent to fit any sized pipe, while the distributors point out that the drive points are hardened so as to be easily driven into the joists. An important feature is the fact that the hanger can be shortened by winding around the pipe, if necessary. Another advantage claimed for the flexible hanger is the fact that one size can be used to take the place of many different sizes previously required.

Montreal Firm Builds Largest Hydraulic Valve in the World

THE rapid strides made in the last ten years in the sizes of water turbine units have naturally called for similar developments in the line of accessory equipment. During the present summer there was installed at Shawinigan Falls, P.Q., a 41,500 h.p. unit, which turbine operates under a head of 145 feet, making 138.5 r.p.m. The last link in the equipment which feeds the water to this turbine is a steel penstock 20 feet in diameter. At the end of this penstock nearest the turbine, is located a Larner-Johnson valve, which is used to shut the water off the turbine, and this valve is the largest of its kind in the world. The valve was designed by the Larner-Johnson Valve and Engineering Co. of Philadelphia, and was built by the Dominion Engineering Works Ltd., of Lachine, P. Q.

Fig. 1 shows the valve assembled in the shop previous to same being shipped. The tapered part of the valve casing, shown to the left in Fig. 1, is made of cast steel, and is composed of four pieces. This section contains the removable seat on which the plunger closes, when it is wished to turn off the water. The first machine operations on this section of the valve casing are to face, drill, spot, and ream the flanges which permit the four pieces to be bolted together to form a circular piece. Fig. 2 shows this work in progress. A large duplex horizontal facing, drilling and boring machine is used. No templates were made for this work. Two of the four pieces were marked off and drilled. Then the four parts were assembled, so that a drilled section was between each section not drilled. Then the locations of the holes in the undrilled sections were obtained by marking same with a scratch awl, using the drilled sections as templates.

As soon as the sections were bolted together work was continued on a large boring mill. The end flanges were faced and the casting bored for the plunger, brass bush, and seat. Some of the principal general dimensions of the valve are: outside diameter of the casing, 23 feet; extreme length, 27 feet; inside diameter of the casing 22½ feet tapering to 13 feet at the outlet. This latter dimension is approximately that of the intake diameter of the turbine scroll casing. The diameter of the cylindrical plunger inside the shell is 16 feet. This plunger has conical ends and can be seen protruding from the casing in Fig. 1. The total weight of the valve is 150 tons and the plunger or moving part weighs 25 tons.

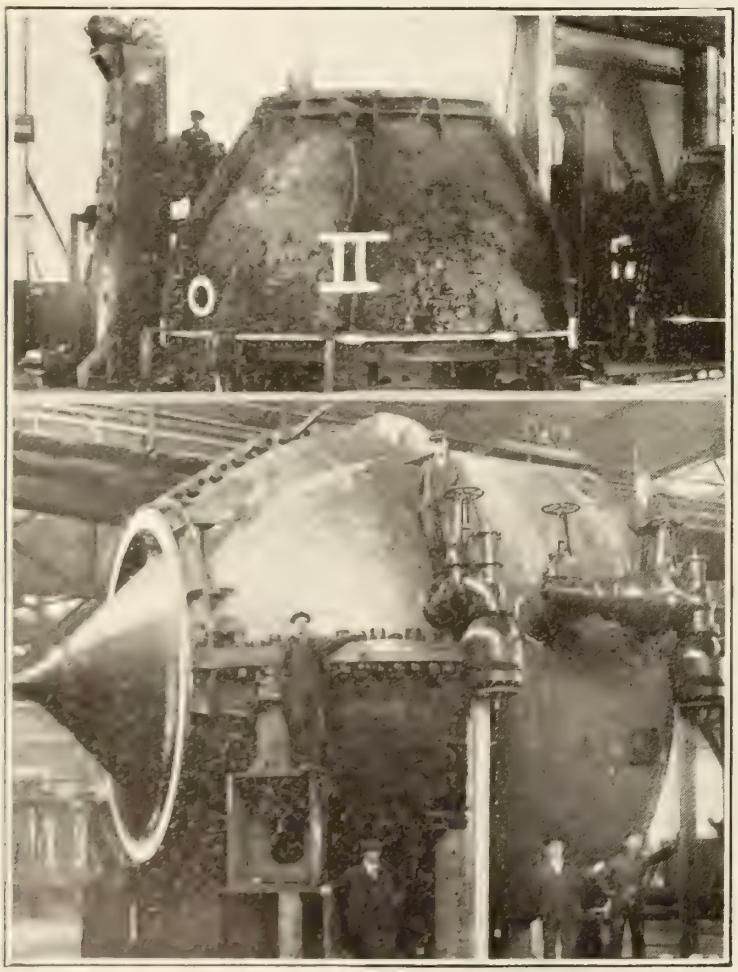

Fig. 1.—Lower: Largest hydraulic valve in the world.
Fig. 2.—Top: Machining the valve castings.

This valve is the largest in the world and is operated by varying the pressure in an annular space, which is located between the casing and the plunger.

That cylindrical section of the valve shown to the right in Fig. 1 is made from heavy steel plate, and rivetted to the cast steel section of the casing. This plate section is rivetted to the 20 foot diameter steel flume. Large brass sleeves line the annular chamber and guide the integral steel rings, (one on the casing, one on the plunger), that seal the ends of the annular space. Thus when the plunger moves, a contact of brass and steel is made.

TORONTO NO. 1 C. A. S. E.

The regular meeting of the Toronto branch of the Canadian Association of Stationary Engineers was held on Tuesday, Aug. 15th, at Cumberland Hall, and despite the uncomfortably hot weather, quite a good turn out of the membership were present. In addition to this, four members were admitted to the branch, and the president, Bro. R. MacLaren, announced that he had the names of a number of engineers who were seeking admittance. After the routine business of the branch had been gone through, which was done in quick order, the meeting was opened for educational purposes. A question which had been deposited in the box, was taken up for discussion. This was, "Does excess air in the furnace raise the temperature of flue gases, and if this is so, why?"

The question was discussed by Bros. Fenner, Soucy, McCarthy, and MacLaren. In this connection it may be mentioned that Bro. McCarthy was one of the new members initiated at that meeting, and he showed the right spirit by rising and joining in the discussion in such a helpful manner. These are the kind of members who are going to lift the C. A. S. E. into the position it should rightfully hold.

It has been decided that the educational sessions will be thrown open to any engineers who wish to take advantage of them, irrespective of whether they belong to the association or not. In this connection it has been decided to give a definite invitation to the local union to join in these educational meetings, so that they may benefit by them.

The educational programme for the session, is again printed in this issue of Power House, and it will be seen that it is an attractive one. With the passing of the summer and the advent of more propitious weather for these kind of meetings, Toronto No. 1 Branch, C. A. S. E. is looking forward to a series of splendid meetings.

The Gennevilliers Central Station

(Continued from August 20th Issue)

Low-tension Switchboard Room

This building, adjoining the preceding on its west side, is also metal framed, but of very light construction, with brick filling, both solid and perforated, and lined with tiles; it is 23 ft. wide and 280 ft. long, enclosing, at a height of 36 ft. above foundations, a gallery 6 ft. 6 in. wide in the lower portion of the building, containing the main transformer switches, and alongside this a span 16 ft. 4 in. wide containing the laboratory and the auxiliary transformers. There are also two other floors at heights of 56 ft. and 69 ft. respectively above foundations; of these, the lower carries the auxiliary 3,000-volt switchboards and the small wiring switches; the upper floor carries the 60,000-volt and also 3,000-volt switchboards, as well as the continuous-current 500-volt board and the three-phase 220-volt board. It also comprises the dispatching gear and the main telephone exchange as well as the air filters arranged at the north end.

Boiler-house

The boiler-house is entirely of reinforced concrete carried on blocks resting on groups of piles. The stanchions, commencing at 109 ft. above foundation level, and the roof principals are the only metal portions of the structure. The boiler-house is 150 ft. wide by 283 ft. long. The roof principals rest on shoes at 160 ft. above foundations, giving 86 ft. of head room in the building.

There are two rows of boilers arranged lengthwise of the building consisting of ten Babcock boilers in pairs with 10 ft. clear way between the pairs, and arranged for firing ultimately with mazout, and the other row consisting of five Stirling boilers. This installation corresponds to the five turbo-alternators to be erected in the power-house; provision has been made for extensions in both the boiler and power-houses. The two rows of boilers are separated by a central gangway 28 ft. wide and at the sides there are gangways 22 ft. wide on the Babcock and 23 ft. on the Stirling side; these are connected by six cross ways each about 10 ft. wide.

A large basement extends under the boiler-house at a height of 33 ft. above foundations, and carries the various railway tracks necessary for removal of clinkers, ash, etc. Above this a floor at 46 ft. above foundations carries the piping, and a third floor at 56 ft. above foundations on the level with the power-house floor forms the actual firing floor. Bins of reinforced concrete are arranged in the ways between the boilers of a size sufficient to contain a total of about 3,800 tons of coal.

This building, arranged to the west of the low-tension switchboard, is constructed entirely of reinforced concrete, the construction consisting of piers and cross members carrying a roof with a slight fall each way. The north and west walls are filled with white brickwork; the south end has a temporary metal end. There is a passage way round the upper part of the building with staircases, and communicating with both the high and low-tension switchboard rooms.

Water Conduits: Intake

This consists of two channels of reinforced concrete 6 ft. 6 in. wide by 14 ft. 6 in. deep separated by a wall 1 ft. thick and both communicating with the common lodge from which the water is drawn.

Return

Under the power-house is a single conduit, 12 ft. 6 in. by 16 ft. 10 in., which is divided on leaving the building into two, measuring 8 ft. 1 in. by 6 ft. 4 in., separated by a wall 1 ft. thick, and arranged obliquely in plan so as to deliver into the river about 450 ft. below the intake. Arrangements are provided for maintaining the water level even in time of drought.

Lodge

The lodge is 92 ft. long by 34 ft. wide, and is arranged with seven inlet channels fitted with screens and strainers for removing dirt and foreign matter from the water; a well sunk below the lodge serves to feed the pumps used for clearing the screens and strainers.

The Quay Wall is built of reinforced concrete with an outer slope of 63 deg., the top being at 34 ft. above foundation level, and is stiffened with reinforced concrete work on the inside. The coal store is arranged 26 ft. 6 in. above foundation level parallel to the river between the main buildings and the river; it measures 650 ft. by 130 ft. It is enclosed by a wall on the side nearest the river and by earth embankments covered with reinforced concrete on the other sides. A traveling gantry transfers the coal to the store. Railway tracks running at the quay level serve for handling wagons.

Plant

The five turbo-alternators are of 40,000 kilowatts each, one being supplied by Escher Wyss (Switzerland), and the others half by the Société Alsacienne de Constructions Mécaniques, and half by Messrs. Schneider and Cie. The steam pressure is 22 kilos. per square centimetre (310 lb. per square inch), and the turbines run at 1,500 revolutions per minute. The alternators have closed-circuit air cooling, with make-up of filtered air; the tension of the terminals is 6.000 volts.

Each turbo-alternator group delivers to three single-phase step-up transformers raising the voltage to 60,000 and connected direct to the high-tension switchboard, where they feed the 60,000-volt bars to which the sub-station feeders are connected.

The particulars of the boilers are:—Working pressure 350 lb. per square inch; temperature of superheated steam, 375 deg. to 400 deg. Cent.; heating surface per boiler, Babcock, 14,000 square feet; Stirling, 22,500 square feet; evaporation per hour, Babcock, 117,000 lb.; Stirling, 176,000 lb; forcing fans and induced draught. The feed water from the condensers is heated to 80 deg. Cent. at the turbine, and further to 100 deg. by the exhaust from the auxiliary machines; then after de-gassing it passes through steel economisers above each boiler, leaving these at about 160 deg. Cen. to enter the boiler. The gases leave the boiler at 340 deg. Cent., and fall to 220 deg. Cent. in passing through the economiser, and then in passing through the air heaters they are further reduced to 150 deg. Cent. The air forced under the grates passes through the heaters, and is raised to about 90 deg. Cent. before entering the fire. The economisers have 13,000 square feet surface for each Stirling boiler and 17,000 square feet for each pair of Babcock boilers. The condensers have 37,000 square feet cooling surface and are supplied by two circulating pumps each capable of delivering 6,750 tons of water per hour (for the whole eight sets, two standing by and six running, this will be equal to 9 tons of water per second).

The level of the yard and works has been arranged to come above the highest flood mark of the Seine.

When fully equipped, the station will have cost a little under 600f. per kilowatt, on the 200,000 kilowatt basis, a figure which will be reduced to 350f. when the output reaches 320,000 kilowatts; this is about the same as the mean figure for installations equipped before the war. The area of power-house per kilowatt is 1.18 square feet, and the area of boiler-house 2.36 feet.

The station is not yet complete, but it has relieved the situation of the supplying companies, which had reached the stage of being unable to supply new demands. The standardising of the three-phase current at 50 periods, which will shortly be effected, will do much to simplify the construction of motors and to reduce the cost to the consumer.

BULLETINS

The Yarnall Waring Co., Philadelphia, have issued a bulletin T-1701 describing "Yarway" steam traps, and this is available to any one interested. The trap is of the bucket type, and possesses several features, which are clearly described and illustrated in the bulletin. A table of prices and dimensions, and one of capacities and weights are also included.

Dangerous Leanings

WE HAVE before us at this moment a despatch published in the "Vancouver Federationist," of Vancouver, B. C. The despatch in question is a report of a meeting of Local 844, Steam and Operating Engineers, and comments on the fact that this local is making good progress in spite of there being a dual organization in the city. It also states that a visit had been paid to the local by the International President, and that he would soon be returning. All this seems purely legitimate Union business, and whether we are in sympathy with the Union or not, calls for no comment. However, we come to a statement that we think does call for comment in these times, and that is: "A delegate was elected to the Friends of Soviet Russia, and the local will, on receiving his report of that organization's activities, take such steps are are possible to render assistance in a practical manner."

What any sane engineer expects to receive from Sovietism or Bolshevism is more than we can imagine. If there is one man more than another who depends on his own individual ability, and willingness to work and study for success, it is the engineer. We feel that these men who are so willing to extend assistance to Soviet Russia, must have but a very feeble idea of the conditions of things in that unhappy country under Soviet Government. We can understand well that charitable people should be anxious to extend help in the way of food to the children who are starving to death, and whose parents have been murdered by this beneficent Soviet. We cannot understand how any man, living in this free Dominion, should wish to change his state for that of the persecuted and slave driven victims of Lenine's experiment in Communism.

We feel that any man who has Soviet or Communistic leanings is not a good citizen of this country, but is a danger to it. We are not familiar with this particular Union, but it is evidently a United States organization. There are some things imported from our neighbors to the South which we would be much better off without. This is a free country, and men have a greater amount of latitude in what they do or don't do than in many other countries, but we feel that when their activities extend to encouraging Sovietism in any shape or form, they should be curtailed.

An Unsatisfactory Situation

SINCE OUR last issue there have been developments in the coal situation which lighten it to some extent, but it still remains sufficiently serious. The miners in Nova Scotia have voted to return to work, and at the time of writing, great hopes are expressed for a settlement of the anthracite strike. The soft coal mines have been producing steadily if not fully all

The greatest drawback still remains, the railway situation which will have as much effect in limiting the fuel supply as actual stoppage at the mines has had. The United States government blow hot and cold on the question of action, and are at one moment going to step in decisively and control everything, but in the succeeding moment arrive at a decision to refrain from doing anything.

In Ontario the fuel controller takes a very serious view of the situation, while the coal dealers seem to take the attitude that everything will come out all right, and therefore there is no need for drastic action. Between all these different opinions it is hard for the average man to make any definite decision.

Viewing the situation from the information available, we should say that as far as industrial plants are concerned, they will be able to fill their requirements. There will, no doubt, be occasion for economy, but it is our contention that this necessity is always present, only it gets greater attention in a time like this. For the domestic consumer, the prospect is for considerable inconvenience, if not actual hardship. We can hardly blame the dealers for not rushing into the market for Welsh coal, which may possibly be left on their hands. As far as municipalities are concerned, we think that the town and city councils should have made a careful inventory of the coal supplies on hand and the prospects of getting new supplies, and taken action before this time to ensure that the community should not suffer or be held up by profiteering dealers.

It is quite possible that many householders will have to burn soft coal in their furnaces this winter. There is no reason why they should not be able to do so successfully. It will require more looking after than hard coal, and on account of it packing together much closer, will require more draft than it is usual to carry with hard coal. The average house has a chimney quite high enough and of ample area to give this draft. What will be necessary is that all joints in the piping are carefully looked over for leaks, and care taken so that the air will all reach the fuel through the grate bars, except what is necessary to pass over the top for burning the volatile gases.

The engineer and fireman can come to the help of his neighbor in a case of this kind, and give him the benefit of his experience, to the mutual advantage of the whole community

A Settlement Reached

BEFORE going to press the news has reached us of the settlement of the strike in the anthracite coal mines. This will be received with great relief all over the continent, and especially in those districts that depend on getting their supply before the close of navigation. The situation is unfortunately far from clear as regards the distribution of the coal when work re-commences. The railways assert that they have ample cars to move all the coal that will be mined, but U. S. Government authorities are not so certain.

Economy must still be the watchword in Canada.

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

CORLISS ENGINE GOVERNOR

Question:—Please describe the power method of adjusting the governor connections on a Corliss engine, and oblige an old reader.

Answer:—In the ordinary type of Corliss, the governing is effected by altering the position of the knock off cams on the valve spindle, to give an earlier cut off. The knock off cams are loose on the valve spindle, and can be turned to any position. They are connected to the governor by reach rods, and as the governor rises or falls the rods are alternately pushed or pulled, bringing the cams closer to the steam hook or further away, making cut off sooner or later. The ordinary method of adjusting is as follows:—First take out the safety stop from under the governor, allowing it to drop to its lowest position. When in this position the cams should be in such a position that the steam hook will not engage. That is the cams are so far round, by reason of the governor being in its lowest position, that the safety lug on the cam has come into position. If when the governor is in its lowest position, the steam hook will still engage, the reach rods must be adjusted until this fault is remedied. The reach rods are usually fitted with right and left hand couplings, so that they can be shortened or lengthened by merely turning in either direction.

Having made sure that the steam valves will not be operated when the governor is in its lowest or emergency position, the next step is to place the safety stop under the governor thus bringing the engine into its proper condition for starting. With the governor resting on the stop, and the engine on the dead centre at either end, the steam valve will be open the amount of lead that has been given it when setting the valves. Now turn the engine round by hand until the half stroke is reached. The knock off cams should release the valve when the half stroke is reached, or just a trifle before. If this is not the case, adjust the reach rods until they give cut off at half stroke. When these conditions are fulfilled, the governor should give the right cut off in any other position. When the engine is running, some further adjustments may be necessary in order to get the cut off at the correct place for the average load, but this can only be determined from the indicator cards.

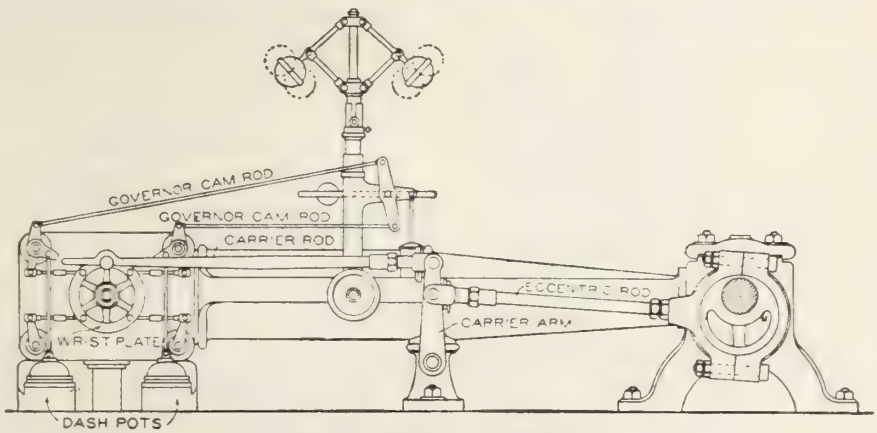

Diagram of Governor Arrangement.

In most governors the normal running position is about half way between the safety catch and the extreme top of the travel, and this can be used as a factor in setting the governor if necessary. Block the governor up to about half way between the position it occupies when resting on the safety catch, and the extreme upper position. Then adjust the reach rods to give cut off at the position of the stroke you want, usually about one quarter to three-eighths stroke. Make further adjustments from the indicator cards. Always remember that the governor, when below its safety stop, which is where it would be if the belt broke or slipped badly, should bring the knock off cams to a position where their safety lugs will be under the steam hook, so that no steam is admitted. Also that when the governor is in its lowest position, that cut off shall take place at half stroke. If these conditions are observed, the remaining adjustment can be made when the engine is running from the indicator cards.

Enlarged view of steam hoop and cams.

STRENGTH OF CABLES

Question:—Will you please tell me in your question box how to find strength of cables, 1⅛th inches diameter, 6 strand, 18 wires to a strand.

Answer:—Cables for hoisting are usually made with 6 strands and 19 wires to a strand, while hauling ropes are made of 6 strands with 7 wires to a strand. The strength varies with the material that the wire is made of. The factor of safety used is about 5, that is the working strength is about one-fifth of the breaking stress. There is a stress on the rope due to bending as well as the direct tension stress due to the weight in a rope passing over a sheave, and for this reason certain minimum diameters of sheaves are recommended. A standard hoisting rope, as given in the tables

based on data supplied by the American Steel and Wire Co. of 1⅛th diameter, 6 strands, 19 wires to a strand, has a safe working load if of iron, of 3.7 tons, crucible steel 7.6 tons, extra strong crucible steel, 8.6 tons, plow steel, 9.4 tons, and monitor plow steel 11 tons.

There is thus a considerable spread between the different kinds of material. The area of a wire rope of 1⅛th diameter of 6 x 19 construction is .45 square inches, which works out for iron at 6.6 tons per square inch, for crucible steel 16.8 tons per sq. inch and so on.

An approximate rule for the strength of steel ropes is as follows:—The circumference squared of the rope divided by 2 gives the safe working load. Thus for a 1⅛th rope the circumference is 3.5 inches, and this squared is 12.25 and divided by 2 gives the safe working load at 6.6 tons. This is an English rule, and the tons would be 2,240 pounds, so that for the 2,000 lb. ton, the result would be 7.36, which agrees very closely with the working strength given in the tables. The same authority gives for hemp ropes the circumference squared divided by 20. For iron chains the number of eights in the diameter of the rod from which the chain is made, squared, and divided by 10¾. Thus a chain made of 1 inch stock would be good for a safe load of 8 x 8 divided by 10 or 6.4 tons.

It is the rule to test a piece of the wire rope of each size to destruction in a testing machine, and these tables have been formulated from the results of calculation and actual tests carried out in this way.

WATER IN CYLINDERS

Question:—What provision is usually made in vertical engines for getting rid of the water that accumulates on top of the pistons? Will not the presence of water in the cylinders materially impair the economy in the use of steam?

Answer:—When warming up, preparatory to starting, and during the first few minutes of running, water of condensation is taken care of by the drain cocks, and also a certain amount is carried away with the exhaust through the slide valve opening. When the engine is running up to normal speed and load, there is usually provision for a sudden slug of water in the shape of a spring loaded relief valve of ample size to relieve the cylinder. In some types of engine the valve itself is held up to the face by a spring, which is heavy enough to hold it under ordinary conditions, but will allow it to lift from the face under a sudden shock such as that caused by the presence of water in the cylinder.

As to the second part of your question, the answer is of course yes. However, we can guard against the presence of water, that is of water being carried over with the steam in large quantities by suitable separators. What we cannot avoid in ordinary engines with saturated steam, is the condensation of a certain amount of the steam on its admission to the cylinder, due to the cylinder walls having been cooled off during the exhaust period of the preceding stroke. This condensation represents a distinct loss. If there is water constantly present in the cylinder the loss is of course considerable, but generally, the condensation which has occurred during admission is re-evaporated during expansion. If the engine is a simple one, that is single cylinder non-condensing, this re-evaporation is of no value as the heat abstracted from the cylinder walls to perform the evaporation is merely carried away in the exhaust. If the engine is a compound one, we get the benefit of this heat in the next cylinder.

EXPANSION VALVES

Question:—Why cannot pressure regulating (or reducing) valves be used in refrigerating systems in place of the ordinary expansion valves?

Answer:—In the ordinary pressure reducing valves there is on each side of the valve a gas, but at different pressures. The temperature on each side is substantially the same. The greater number of these valves function by the difference in area of two diaphragm surfaces, counterbalanced by a spring or lever. These valves have large clear passages, and having practically the same temperature on each side, are not affected by unequal expansion problems. The expansion valve in the refrigerating system has a very different duty to perform. It has to pass a fluid under high pressure and comparatively high temperature, through a small opening to a chamber in which both pressure and temperature are considerably lower. The fluid in passing through the small orifice can be throttled down to an infinestimal amount, and the valve is so constructed that the slightest movement of the orifice gives a definite adjustment. There are no diaphragms, levers, etc., to cause trouble. It would be impossible to obtain the fine adjustments necessary with the ordinary pressure regulating valve, even if the problem of expansion and contraction could be overcome. In a nutshell, we might say that the ordinary pressure reducing or regulating valve is for handling large volumes of a gas at different pressure but approximately the same temperatures, while the refrigerating expansion valve is for handling comparatively small volumes of fluid, at greatly different temperatures on each side of the valve, and giving extremely close adjustments of flow to suit varying conditions.

NON-RETURN VALVES ON BOILER

Question:—When non-return valves are used in the connection between a battery of boilers and the steam header, in addition to the regular positive stop valves, should the non-return valves be placed next to the boilers, or next to the header? What are the reasons?

Answer:—The non-return valve is usually placed on the steam pipe, between the boiler and the non-stop valve, or in other words, next to the boiler. As the object of the valve is to prevent the steam from the header rushing into the boiler in case of any sudden drop in pressure, it is placed close to the boiler and the main stop valve. In fact it is very often made a part of the main stop. There is no particular reason why it should not be placed next to the header, except that it would not be possible to overhaul it when the boiler is shut down if it were between the boiler stop-valve and the header. It is much the same reason as makes us put the feed check valves against the boiler instead of at the pump.

SIZE OF MAGNET

Question:—Please inform me of the size of plunger, amount of wire, etc., for operating a solenoid to lift 5 lbs. on 440-volt, 60-cycle A. C. current.

Answer:—

Your question concerning the size of plunger, amount of wire, etc., for operating, a solenoid to lift 5 lbs. on a 440-volt A. C. circuit of 60-cycle is a most difficult one to answer; as there are so many varying factors, each of which must be firmly established before we can determine the results.

The first point which arises is—What is the permeability of the iron used for a core? This in turn will determine the value of the flux density, which in turn determines the exact "lifting power" of the magnet.

The permeability varies with each grade of iron, and can only be determined experimentally. This is the deciding factor, yet it varies within the following wide limits. Cast iron from 12,000 to 70,000 lines per sq. in., wrought iron, from 20,000 to 140,000 lines per sq. in.

Obviously therefore to attempt the correct magnetization of the core without being in possession of this figure, would be somewhat of a wild guess. The following is the detail of a solenoid for work under somewhat similar circumstances as mentioned in your letter.

Length of solenoid 5 in.; internal dia. 3 in.; external dia. 4½ in.; dia. of plunger 2⅜ in.; stop projects inside solenoid 1½ in.; air cap ¼ in.; turns of wire 144; volts 220; frequency 60; current 8 amps.; pull 5 lbs.

The general rules to follow are:—

(a) The traction of a magnet in pounds is equal to the square of the number of lines of force per sq. in., multiplied by the area of contact and divided by 72,134,000.

(b) The reluctance of a core or any portion thereof for inch measurements is equal to the product of the length of the core by 0.3132 divided by the product of its cross-sectional area and permeability.

(c) To calculate the magnetizing force in amp-turns required to force a given number of magnetic lines through

(Continued on page 38)

The Operators' Point of View

Test of Electrical Boiler

By M. C. ALLEN

ON ACCOUNT of the recent introduction and use of the high voltage electric boiler for the generation of high pressure steam for power and heating purposes the writer thought that the following description and test results might be of interest to some of your readers.

This particular boiler was especially fitted up for testing purposes and extreme care was used in the use and calibration of the measuring instruments. Some of the instruments used are similar to those used in a similar test on a coal-fired boiler and some are different on account of the difference of the material used to generate heat—electricity in one case and coal in the other. The sampling, weighing and analysis of coal are done away with as also is the gauging of draught, the analysis of flue gas and the weighing of ashes. All of this information being given by the reading of the wattmeter and then changed into B. t. u. or Boiler Horse Power.

The measurement of the water turned into steam is more difficult in an electric boiler than in the coal-fired boiler on account of the large loss in the blow off and the necessity of measuring the loss to get an accurate idea of the performance of the boiler.

The blow-off water usually leaves the boiler at a temperature above 212 degrees and in addition sometimes contains a certain part of the heat of evaporation which is given off as steam as soon as the water leaves the boiler and the pressure reduced to atmospheric. An accurate method of measuring the heat loss would be by means of a condenser. The test figures will show that it is considerable. Of course the steam generated can be measured by a steam flow meter and corrected for moisture and pressure, but to give an accurate and complete test report the blow-off should be determined. The large quantity of water blown off is necessitated by the type of construction of the boiler and the use of high tension electricity for steam generation. The generation of steam by electricity in the boiler on which these tests were made depended on the resistance of the water to the passage of the electric current and clear water has a higher resistance than muddy water. The particles of sediment in the water form a good conductor for the electric current and if the water is allowed to become too muddy it will probably result in the current arcing from electrode to the boiler shell and result in the destruction of the boiler. This condition necessitates the frequent use of the blow off valve to keep the water clean.

The feed water for the test may be measured, weighed, or metered as desired. In these particular tests it was measured in a calibrated tank and pumped from there to the boiler. The dryness, temperature and pressure of the steam were taken in the usual manner.

The following are the average results obtained:

Duration of test—5 hrs. 54 minutes.

Average Pressures, Temperature, Voltage, K. W., etc.

Steam pressure by gauge—124 lbs. per sq. inch.
Temperature of feed water—120 degrees F.
Temperature of blow-off water—187 degrees F. (when measured).
Average voltage—5,900.
Average amperes—1,254.5.
Average K. W. hours—12,425.
Percentage of moisture in steam—4.6%.
Quality of steam—95.94%.
Temperature of steam in calimeter—228.9 degrees.
Pressure in calorimeter—5 lbs.

Total Quantities

Weight of feed water supplied to boiler—251,140 lbs.
Total water blown off from boiler—32,605 lbs.
Water from steam separator—475 lbs.
Water carried over in steam—8,950 lbs.
Water turned into steam allowing for loss of blow-off, trap and moisture in steam—209,110 lbs.
Steam generator per hour—35,700 lbs.
Factor of evaporation—1.17.
Equivalent of evaporation per hour—41,700.
Boiler H. P. developed—1.210.
K. W. required per B. H. P. hour—10.36.
Boiler efficiency—94%.
Rated capacity of boiler—1,500 H. P.
Per cent. of rated capacity developed—81%
K. W. hours required to generate 1 000 lbs. of steam at 149 lbs. pressure.—349.

Comparative Cost of Steam and Electric Power

With coal at $8.00 per ton and a fair boiler and operating efficiency, steam may be produced for about 50c. per 1,000 lbs. from and at 212 degrees F.

To produce steam at this figure by electric power the cost would have to be about $9.35 per h. p. year. This figure is much lower than the rates usually paid for electric power but if power is purchased by contracting for a certain number of h. p. for a certain time an electric boiler may be profitably operated, particularly if the power requirements are not up to contract. A 1,500 h. p. electric boiler occupies less space and requires less care than a 300 h. p. coal-fired boiler.

These figures and description are intended to give a general idea of the operation of electric boilers in use at present in large pulp and paper and other manufacturing companies and also to give a comparison between electric and coal-fired boilers as regard cost of power, etc. They are not intended to cover any points of design, operation or mechanical description of the boilers.

HIGH WATER IN BOILERS

A great many articles have been written about the dangers of low water in steam boilers. It must be admitted such danger is real and to be avoided as much as humanly possible by using all known precautions. Although high water has been responsible for about as much material damage as low water, little comparatively has been written about it. How many engine wrecks have been caused by high water we shall never know. How many steam mains have been ruptured by water hammer due to high water? Such an accident may lead to a boiler wreck and great property loss and it may be impossible to prove that high water was the cause. I imagine if it were not for the steam separators, high water would have many further serious losses charged against it. Of course high water or a foaming boiler can cause an engine wreck even where there is a separator in use as such a separator may not be of sufficient capacity to handle a large charge of water. A foaming boiler is very often due to the same cause as high water. that is, neglect on the part of the boiler attendant. A clean boiler seldom foams and attention to duty will prevent high water. Of

course there are exceptions. Some engineers have not a good word to say for the high and low water alarm. In my opinion their use has saved vast sums of money by preventing accidents. One of the reasons given against their use is that they are apt to make the boiler attendant careless. Just the opposite, I would think, for the alarm whistle will inform the chief if the boiler attendant is not attending to his duty. Another detrimental reason given is that such alarms can get out of order, and an accident occurs because of the attendant placing reliance upon it. The same can be said about the safety valve, but that is no reason why we should discard it. Believe me, high water is a bad condition, pretty near as serious and undesirable as low water, and it is a great deal more common. Some boiler attendants will fill the boiler to the highest possible level right up near the top of the glass. Especially is this so in some localities where there is no uniform call for steam. Where the consumption is nearly constant the experienced man generally has his feed set so that the water level is on the same lines. We always hear of a serious boiler explosion, or other serious damage caused by low water, but there are many cases of serious damage caused by high water that are never publicly charged up to the real cause. A defective fitting broken by expansion or contraction according to report is perhaps due to water hammer. Such an accident on a large high-pressure steam main might be nearly as serious as a boiler explosion.

C. A. S. E. PICNIC

Toronto, No. 1 Branch of the Canadian Association of Stationary Engineers held a most successful picnic in the Exhibition Park, Toronto, on Saturday afternoon, August 19th. A long programme of sports was run off, during the afternoon, while at the close of the strenuous exercises, an informal supper was served in one of the buildings.

While all the sporting events were good, the baseball game between those earnest competitors, the supply men and the engineers, supplied the cream of the entertainment. While there was some doubt as to whether it was indoor or outdoor, hard ball or soft ball, everybody enjoyed it. Mr. Gordon Keith, after receiving the ball on the point of his jaw, inclined to the view that it was a hard ball, or in any case, hard enough for him. Notwithstanding this inauspicious start, Mr. Keith had the courage to accept the position of umpire on bases.

After the usual preliminary conversation, the game was started, and the supply men speedily demonstrated their superiority. Mr. Jack Thompson, who was catching for the supply men, not only displayed great agility in fielding his position, but was a mountain of support to the pitcher by reason of the valuable advice which he freely dispensed. In addition to this, after every pitched ball, he delivered a lecture on the rules of the game, which was greatly enjoyed by everybody but the players.

The umpire behind the bat, Mr. Walter Blackgrove, was eminently fitted for the job, not from any particular acquaintance he had with the game, but because he is the possessor of a stern and forbidding presence, and a voice like the bos'n's mate of the "Billy Rough 'Un." At that it took him all his time to be heard above the raucuous shouts of the aforesaid Jack Thompson.

The result of the game was a victory for the supply men, but this was only made possible by the supply men enlisting the help of the editor of "Power House" over the protest of the engineers. With the sun fast sinking, and both sides showing signs of exhaustion, the editor came to bat, and produced the hit that brought in the run that won the game for the supply men.

This was extremely fortunate, as all the available pitchers and catchers on both sides had been used up, and there was no more room on the score sheet to put down further runs.

The following is a list of the prize-winners and the donors of same:—

(1) The Tallest Engineer—Mr. F. A. W. Taylor; steel rule in leather case; 2nd prize, Mr. Jno. Brown; one year's subscription to Power House.

(2) The Shortest Engineer—Mr. R. Mallory; steel rule in leather case; 2nd prize, J. T. Onyon; one year's subscription to Power House.

(3) The Stoutest Engineer—Mr. S. B. Hall; Veeder speed-counter; 2nd prize, Jno. Brown, book on "How To Eat and Reduce."

(4) The Thinnest Engineer—N. Smith; book, "An Engineer's Lamp;" 2nd prize, E. Hurst; one year's subscription to Power House.

(5) The Oldest Engineer—J. Halliday; "picture of the Duke and Duchess."

(6) The Oldest Woman—Mrs. W. G. Blackgrove; book, "Why Grow Old?"

(7) The Youngest Woman—Mrs. A. Martin; box of Cowan's chocolates.

(8) The Fairest Woman—Mrs. E. Osborn; box of Cowan's chocolates.

(9) The Darkest Woman—Mrs. T. H. Turner; a parasol of darker hue.

(10) Sphinx-like—Mrs. Jno. Brown; box of Cowan's chocolates.

(11) The Grand Tormentor—Mr. A. P. Black; Tantalus-glass (Ontario).

(12) Boys' Race (50 yards)—E. H. Perkins, Jr., E. Bruce and D. Perkins.

(13) Girls' Race (50 yards)—Annie Hurst, Annie Bruce and Bessie Clews.

(14) Youths' Race (100 yards)—Geo. Brown, Jr., E. Truelove and E. Bruce.

(15) Maidens' Race (100 yards)—Vera Rowe, Miss Wilkinson and Vera Harris.

(16) Men's Race (50 yards)—Jno. Thompson, A. Martin and A. Hunter.

(17) Dairymaids' Race—Mrs. E. Osborne, Miss O. V. Harris and Miss M. Wilkinson.

(18) The Supplymen's "Hop-skip-and-jump"—F. Downs (20 ft. 7 inches), A. Martin (20 ft. 5 inches), and Mr. Jno. Thompson, President of the Supplymen's Assn., (20 ft.).

(20) The exact steppers were:—H. Chandler (90 ft. 11¾ in.), Jno. Brown (99ft. 11½ in.).

(21) The following won distinction as expert smokers:—H. Chandler, C. J. Parker and R. Dunton.

A valuable shaving set was donated as a prize by the Stephens Chemical and Manufacturing Co.

The Veeder speed-counter was donated by the McLean Stoker Co.

Mr. L. J. Ellis, Grand Secy. of the C.A.S.E.accompanied by his wife, from Hamilton, Ont., attended the picnic and was given the Engineers' "Tightener" or the "Grip" that never fails, in the shape of an 18 in. Trimo, as a token of appreciation by Toronto No. 1 C.A.S.E.

The B. F. Sturtevant Co., Hyde Park, Boston, have issued a bulletin descriptive of the Sturtevant underfeed stoker. The bulletin is designated No. 294, and contains a full description and several illustrations of the stoker. The stoker is known as the "Sturtevant R."

C. A. S. E. Members and Guests at Toronto No. 1 Branch Picnic.

Fuel Economy From Old Plant Equipment

By A. R. MUNFORD, U.S. Bureau of Mines

THE fuel economy of a plant may be better than its anxious friends realize. A superintendent of a Government plant, knowing that improvements in plant equipment had been made since his stokers were installed, was almost persuaded to substitute a new type. The Bureau of Mines was asked to ascertain the actual performance of the old stokers and found the plant already doing from three to five per cent. better than was promised for the new equipment.

The value of accurate knowledge of plant performance, and the need o equipment to weigh and measure quantities is thus demonstrated. The boiler and stoker efficiency was found to be 75 per cent., and the overall efficiency of the boiler, stoker, and economizer was 78 per cent. Both records are high, and are to be attributed to care in operation, to good working condition of the plant, and to the low rate of evaporation, which was only about two-thirds of the boiler's rated capacity.

The plant tested consisted of two water-tube boilers fired by means of overfeed stokers and equipped with a fuel economizer in the uptake. The boilers supplied steam to two large water pumps. One of these pumps was operating continuously, the second pump being used only intermittently.

The results of the tests, appended in the table below, were computed from readings collected over a period of 100 hours, from 8:00 a.m., Monday, May 30, to 12:00 noon, Friday, June 3, 1921. The flue-gas losses were determined by analyzing gas samples and observing gas temperature for 20 hours with one water pump running, and for 16 hours with two water pumps running.

The coal was weighed in large truck loads as it was brought from the storage space.

The water fed to the boilers through the economizers was metered by a water meter as it left the feed pump. The meter was tested before and after tests by weighing water passed through it. The meter was read every hour both day and night. The temperature of the water as metered was read every four hours during the test from a thermometer inserted in the feed pump suction line. The temperature of the water as it entered the economizer and as it entered the boiler, after passing through the economizer, was observed every 30 minutes each day and every four hours each night, by means of thermometers inserted at corresponding points in the boiler feed line. The pressure of steam in the boilers was read every hour both day and night.

The level of the water in the boilers was brought to the same point at the end of the test as it was at the beginning.

The temperature of the gases leaving one of the boilers was measured by an exposed copper-constantan thermocouple which was inserted into the center of the opening through which the gases left the boiler. The proximity of the two banks of boilers at the plant made it impossible to place a thermocouple in the corresponding position on the other boiler. This temperature was recorded every 30 minutes during each day.

The temperature of the gases leaving the economizer was measured by two exposed copper-constantan thermocouples inserted at the vertical center and spaced equally across the width of the opening through which the gases left the economizer. These temperatures were recorded every 30 minutes during each day, and their average was taken as the temperature of the gases leaving the economizer.

Samples of gas were drawn from each of the points at which temperature measurements were made; that is, one sample as the gases left the boiler and one as the gases left the economizer. The samples were drawn continuously over half-hour periods during each day and analyzed in a water Orsat.

The coal samples were obtained from a pile made by throwing one shovelful aside for every 20 that were thrown into the weighing car. This pile was reduced by crushing and quartering to the three five-pound samples sent to the chemical laboratories of the Bureau at Pittsburgh for analysis.

All of the ash removed from the furnace during the test was weighed and dumped in a single pile. This whole pile was reduced by crushing and quartering to the three five-pound samples on which the analysis was made.

The average figures and the results of the test are given in the following table:

Results of Tests of Two Boilers and Economizer

RESULTS OF TESTS OF TWO BOILERS AND ECONOMIZER.

	General particulars—equipment.		
1.	Type of boilers		Water tube
2.	Type of economizer		Green fuel economizer.
3.	Type of stoker		overfeed
4.	Heating surface, each boiler	sq. ft.	2,058
5.	Heating surface, both boilers	"	4,116
6.	Heating surface, economizer	"	1,843
7.	Grate surface, each stoker	"	45
8.	Grate surface, both stokers	"	90
9.	Production of draft		Chimney
	General Information.		
10.	Duration of test from 8.00 a.m. May 30 to noon June 3, 1921	hours	100
11.	Duration one pump and auxiliaries running	"	49-2/3
12.	Duration two pumps and auxiliaries running	"	50-1/3

Progress in New Equipment

NOVEL TYPES OF CONDENSER

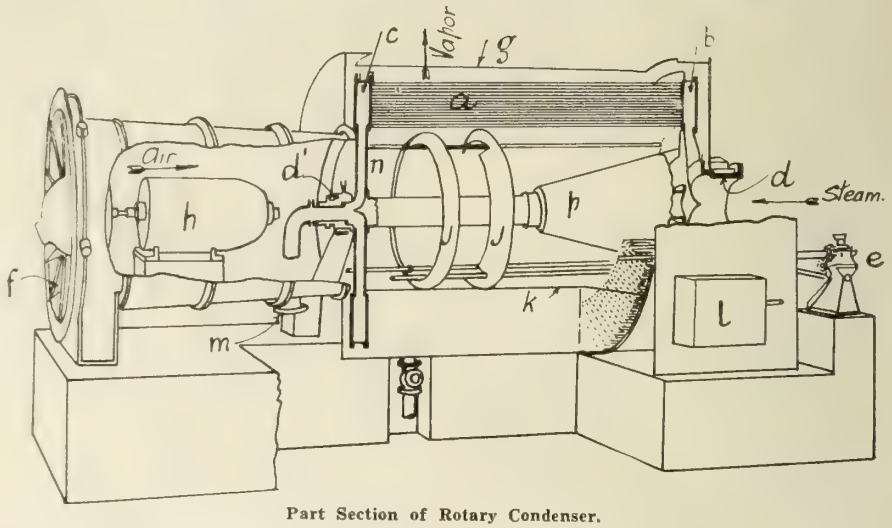
It is somewhat surprising, considering the continued advances made in the steam engine and steam turbine, that little out of the ordinary has been introduced in the condenser line. While admitting the efficiency and reliability of the orthodox types of surface and jet condenser, there are conditions which, to say the least, are not favorable to either type.

The jet condenser will use less water than the surface, but it must be of a quality which is not detrimental to the boiler feed if the condensate is fed back again, while if the quality of cooling water is limited, means have to be taken for cooling it in connection with surface condensers.

Both the ejector and barometric types present special advantages in certain cases, and are now pretty well known, the two types under discussion being comparative recent introductions having several interesting features.

The Ramsey Rotary Condenser

This condenser is claimed to be capable of maintaining a 29 in. vacuum with a consumption of cooling water of not more than 1 lb. per lb. of steam as against the usual 30 lbs. for a surface and 20 lbs. for a jet condenser.



Part Section of Rotary Condenser.

Referring to Fig. 1 it will be seen that it consists of a series of nests of tubes a so arranged to form an annular ring with a chamber b at one end to form a receiver for steam to be condensed, and a chamber c at the other end to form a receiver for the condensed steam and air vapor. Each of these chambers have trunnions d and d' formed on them which serve the double purpose of forming carriers, and also steam inlet and outlet for condensed steam and air vapor, the latter being withdrawn by means of an air pump.

The whole is capable of being rotated through the gearing at e, so that every tube is in turn immersed in the tank k containing condensing water and rises out of the tank covered with a film of water.

Exhaust steam enters through the trunnions d at one end, passes through the header b to the inside of the tubes a where heat transmission takes place, the heat from the steam passing through the tubes and evaporating the film of water on the external surface.

The condensing water which clings to the tubes having evaporated, the heat of evaporation will have been extracted from the steam passing through the tubes which becomes condensed and forms a vacuum. The condensed steam then passes along and out of the tubes into header, through trunnion d' to the outlet pipe m and thence to the air pump.

To remove the vapor of evaporation, and also to enhance the cooling effect on the tubes a fan f either belt-driven or driven by motor h, forces cooling air into the annular space n at center of tube nests. The air passes out among the tubes to an outer casing, the baffles j j and cone p assisting even distribution.

(Continued on page 36)

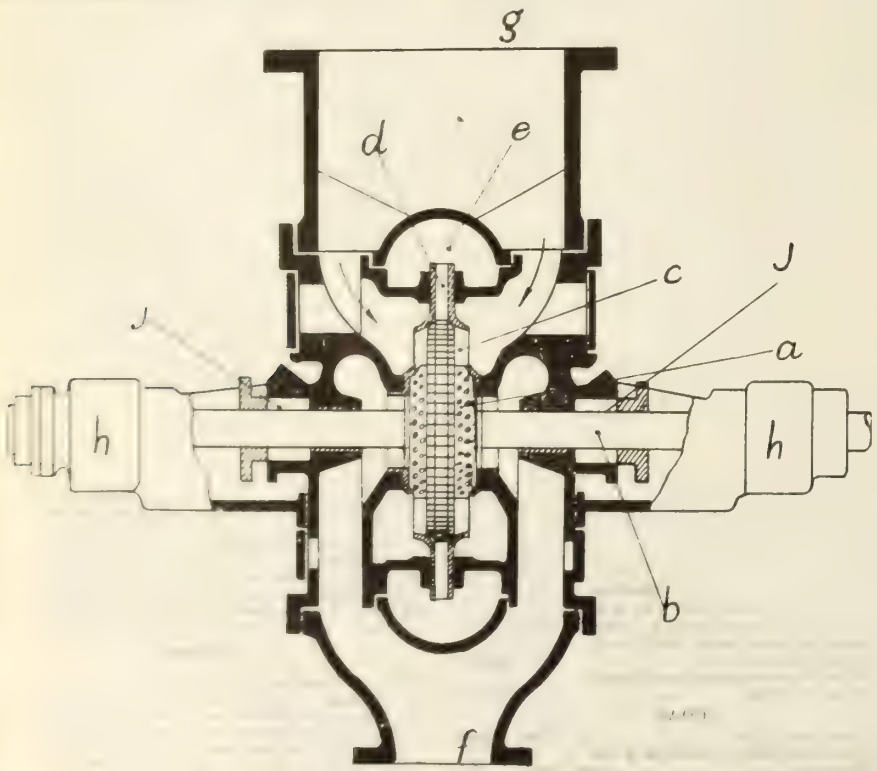


Diagram of impeller condenser.

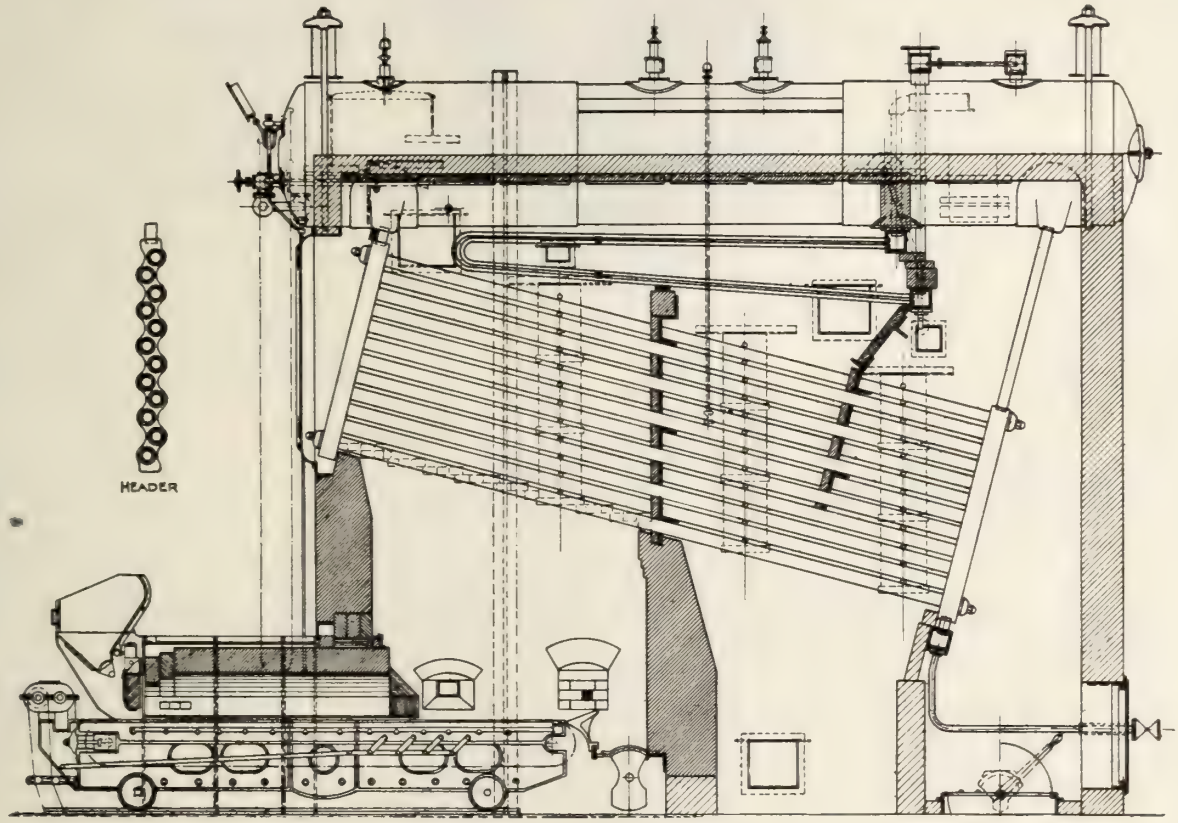
BOILER EFFICIENCY



Standard Longitudinal Drum Sectional Header Boiler

The laws of each province provide that every boiler operated within its boundaries must be built to certain recognized standards. All details such as seams, riveting, fittings, etc., must meet the approval of their inspectors before they will pass any boiler as safe to operate.

The Civil Law also states the lowest grade of engineer you can employ and how often he is required to prepare each boiler for inspection.

The lawmakers are concerned with the safety of the public, they do not make it compulsory for you to buy economical plant. You are expected, on your own judgment as a business man, to buy boilers which will give you the highest degree of safety and the greatest return for your money in pounds of water evaporated.

Now just as there are Civil Laws to make sure no unnecessary risks are taken by the public, so there are certain acknowledged engineering laws for the design and construction of economical boilers and furnaces. The success of all such equipment depends upon the success with which these laws, which safeguard your money, are applied—practically.

Boilers made by B. & W. are readily accepted by the authorities, even in the provinces with the stiffest requirements, because they are designed with a higher factor of safety than asked for, and no steam apparatus is made of better material or with more care. Every part is readily accessible inside and out, and with a responsible man in charge to see they are kept clean, there is little possibility of serious trouble.

As regards the efficiency of B. & W. steam plant, we can only ask you here to consider two factors—(1) THE EFFICIENT FURNACE because the fuel is fed evenly and intermixed with a proper amount of air while burning. Perfect combustion is produced and the fuel all gasified in the large combustion chamber before the heating surfaces are reached. (2) THE EFFICIENT HEATING SURFACE because of the proper circulation of the water and hot gases with reference to each other, and because they thoroughly interpenetrate each other, due to the arrangement of the baffles and the manner in which the tubes are staggered.

Branch Office: Bank of Hamilton Bldg., TORONTO

A NOVEL CONDENSER

(Continued from Page 34)

The water in k is kept at a constant level by the ball valve 1. The tubes a are made of brass, copper or other good heat-conducting metal, and they are carried by means of tube plates fixed to headers b and c, the latter having hollow trunnions concentric with the annular rings of tubes.

These trunnions are carried on pedestals attached to the tank which forms the base of the apparatus. The headers b and c are divided up by means of vanes, forming the tubes into four or more nests, each nest in turn having the steam shut off by means of directing pipes which cause the steam to pass through the tubes which have left the water in the tank and are covered with a thin film of water only.

The trunnions are made water tight by means of packing glands combined with a water seal.

The complete apparatus consists of condenser and fan as shown and an air pump. All three units can be driven by one small engine or electric motor, or separate motors can be applied to each unit as desired. For small and medium size installations where water is scarce the apparatus seems to offer special advantages, the high vacuum and the very small amount of water used being, of course, the special points in its favor.

The Rotary Jet Condenser

This is quite a different proposition to the one previously described. The chief aim of the designers in this case has been to produce a machine that will condense the steam in the minimum of space with a low expenditure of power and in the simplest manner. It is really a development of the Rees-Roturbo centrifugal pump and by referring to Fig. 2 it will be observed that a single rotating portion of the apparatus performs three distinct functions. This rotating member consists of a hollow impeller a keyed on to the main shaft b.

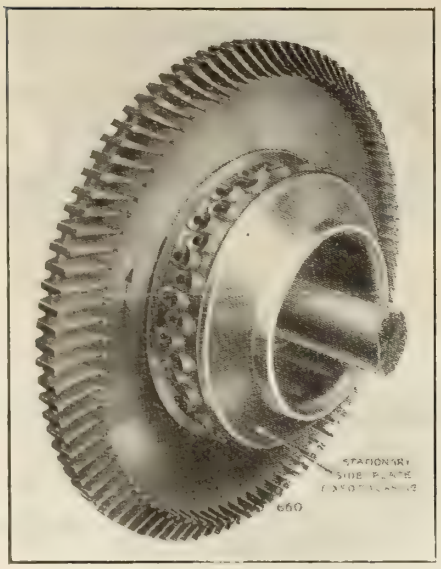
To the periphery of the impeller there is attached a disc c carrying a series of fan blades, the combination of impeller, disc and fan blades forming one complete rotating member.

A general view of the impeller is given in Fig. 3 (electro).

Concentric with the rotary portion of the air pump are a series of fixed blades or diffusers d and concentric with these again is the pump casing e communicating with the outlet.

The operation of this pump is somewhat peculiar but very effective. As soon as the impeller is run up to speed the water is drawn in through the branch f and enters the impeller axially at the sides and issues under considerable pressure radially through the holes shown in Fig. 3. These holes which form nozzles are arranged to impinge on a stationary deflector plate at a fixed distance from the central portion known as the pressure chamber.

A series of radial fans of water are thus formed, which, while still rotating with the impeller are projected across



View of impeller.

the space between the impeller and the inner circumference of the rim containing the fan blades. The steam entering through g and following the path of the arrows meets these rotating jets of water and is carried across the vacuum space to the inner edge of the fan wheel where the mixture of air, steam and water is picked up by the blades (see Fig. 3) and ejected through diffusers d into e and thence to the hotwell.

Thus the impeller lifts the circulating water, produces the jets and finally ejects the condensate.

By this process a perfect mixture of steam and water is ensured, which is an ideal condition for rapid condensation.

The shaft b is packed by glands at j each having separate water seals, and it runs in ring-oiling bearings h. The condenser may be driven by electric motor or high-speed engine, or even steam turbine.

The construction generally is of cast iron but the impeller a and diffuser d are of bronze. The discharge from e is at the side while a vacuum breaker (not shown) is also provided. The discharge is dealt with either by a cooling tower or spray coolers as desired, the former, of course, requiring a separate pump, otherwise no separate lifting pump is required, while the machine is noiseless and capable of utilizing dirty injection water.

Duplex condensers of this type have been built capable of dealing with 90,000 lbs. of steam per hour giving a 28 in. vacuum, the smallest size having a capacity of 4,000 lbs. of steam per hour with a 26 in. vacuum.

BELT DRIVE ECONOMIES

By N. G. Near

Very often, when installing a new driving pulley on a lineshaft in the machine shop the problem of proportioning the driving elements, not only for first cost of installation, but for economical upkeep arises. Generally the diameter of the pulley is assumed and the width of the belt is determined by a formula or heavy, wide, expensive belt. Since the rule of thumb. This often results in a revolutions per minute of the shaft are generally fixed, they cannot be changed without altering practically the entire arrangement in the machine shop. By increasing the diameter of the pulleys, a greater lineal speed of the belt is attained. This also increases its driving power per inch of width and so will allow a narrower, less costly belt.

The writer knows a company that wanted to transmit 20 horsepower from a shaft running at two hundred revolutions per minute to another shaft thirty feet away which was to be run at the same speed. The man who had had considerable experience with belts, and who should have known better, used his "judgment," which told him that two-foot pulleys would be sufficient for the job, and on those pulleys he would use a ten-inch double ply leather belt. He struck the belt width fairly close because a good rule to follow for selecting double-ply leather belts is to allow each inch in width, running at 500 ft. per minute, to transmit one horsepower.

The peripheral speed of a two-foot pulley running at 200 revolutions per minute is 1,255 feet per minute. Each inch in width will, therefore, transmit 2.5 horsepower and a ten-inch belt would easily transmit five horsepower. This man's judgment was, in this case, on the side of safety, but his judgment was not on the side of dollars and cents of economy. "How much will it cost?" he was asked by his superior. "Two hundred and forty-five dollars," was his answer. A little figuring on the part of the man higher up who happened to be better versed in belt matters showed that by using a fifty-two-inch pulley, and a seven-inch belt, the cost would be only one hundred and sixty dollars. The eighty-five dollar difference decided the question in favor of the larger pulleys, to be sure. Of course, there is not always room for as large pulleys as extreme economical considerations would dictate but often larger pulleys may be used to advantage.

The Atlas Engineering and Machine Co., Toronto, have purchased the patent rights and manufacturing rights for the Atlas Positive Circulators for hot water heating, and are now placing them on the market. The Atlas Circulator is the invention of H. H. Angus, B. Sc., Toronto, and consists of a circulating pump direct connected to a motor, the impeller of the pump being of a special design. It is of a conical shape, and will allow water to flow through it freely by gravity when the pump is not in use, so that a stoppage of the pump will not interfere with the circulation in the system. Deflector blades are fitted to impart a straight way motion to the water after leaving the impeller. It is claimed that a much higher efficiency can be obtained in the ordinary hot water heating system by the use of this circulator. The impeller shaft is mounted on ball bearings, the shaft being of special non-corrosive metal, and the bushings of phosphor bronze.

AN EMERGENCY FUEL

As an emergency fuel, a mixture of fuel oil with fine coal in as large proportions as the coal will absorb and hold is suggested by the United States Bureau of Mines to steam coal users and gas manufacturers to augment their fuel supply during the present shortage.

Slack coal that has a high percentage through an 8-mesh screen, or which may be crushed to sizes of one-eighth inch or less, will take up in oil from 30 to 40 per cent. of its own weight and make a fuel high in calorific value. Coarse, slack coal, however, as judged by a representative sample from the Pittsburgh market, will absorb oil to only 3 to 10 per cent. of its own weight, which would give a fuel having only about 4 to 15 per cent. increased heating value. The finer the size of the coal, therefore, the larger is the amount of oil which will be held. Tests made by the Bureau of Mines at its Pittsburgh experiment station indicate that the mixture can be made with either bituminous slack or anthracite culm.

This method bears a relationship to the Trent process of purifying coal by fine grinding and amalgamation with oil, now in operation at a plant at Alexandria, Va., which has demonstrated the success of a combination of oil and coal for steam-making, gas manufacturing and other fuel purposes. The present emergency proposal does not contemplate the cleaning process, but involves merely the simple mixing by shovel or concrete mixer. The Trent Corporation has volunteered to assist the government in advising in the use or application of oil-coal mixtures, and to waive during this emergency any claim of infringement of its process which may or may not be involved by the simple mixing of fuel oil and coal, without reference to cleaning.

An oil refinery at Baltimore, it is reported, mixed by shovel a ton of heavy Mexican fuel oil with two or three tons of western Maryland slack coal, and used it successfully in a switch engine. At the experiment station of the Bureau of Mines at Pittsburgh, it was found that mixtures containing one ton of Mexican fuel oil and four to five tons of Pittsburgh slack coal could be used in a hand-fired furnace.

In using oil-coal mixtures, the fire will smoke badly after firing, or while breaking up the coke bed from time to time. From such limited amount of testing as has been done by the Bureau of Mines, it was shown that careful firing is required to prevent continuous smoking. Experimenting must be done in each case to determine the best method of firing.

Chain grates and certain other automatic stokers are probably well adapted to handle the oil-fuel mixture if the bin and feeding devices are suitable. Oil-fuel mixtures will not fire spontaneously, but undoubtedly care should be exercised to ventilate bins where external heat may tend to drive off lighter gases, although the fuel oil which is on the market has had the lighter oils distilled from it.

Anthracite culm or dust which would sift through ordinary grate bars can be used successfully when mixed with the oil, as the oil causes it to adhere and the oil residue cokes as soon as heated. Oil and anthracite mixtures are not smokeless with hand-firing, the Bureau of Mines tests indicate.

This simple mixture of fuel oil and coal is proposed by the Bureau of Mines merely as a temporary measure. While under conditions of normal fuel supply such a mixture probably would not prove satisfactory unless it involved the cleaning feature embraced in the Trent process; in places where fuel oil is available it can be used to piece out a poor coal supply without the changes in equipment necessary to convert boilers to oil burning.

SAFETY FIRST

"Safety first" is a good maxim in most things, but particularly so in relation to the investment of money. The rich may afford to speculate and to take the risks attendant on high rates of interest. Those whose means are moderate must be careful to see that there is absolute security in their investments. For such people there is no other form of investment which takes such a high rank, combining absolute security with liberal interest, as the bonds of the Dominion of Canada. Holders of Dominion

WE GUARANTEE that with the use of CYCLONE SHAKING AND DUMPING GRATE any grade of hard or soft coal, **or screenings of same,** can be burned with excellent results both as regards Economy and Capacity; that the total annual expense to the user for coal, interest, depreciation, repairs, damage to boiler, liability of shut-down, etc., will be much less than would be the case with any other type of Grate or Stoker on the market.

Anthracite Waste Burned In Pulverized Form

A Test Run Over a Period of Thirty Days on the Boilers of a French Mine—The Fuel Contained a High Ash and Low Volatile Content

A SERIES of conclusive tests on burning mine waste, which have attracted considerable attention among French engineers, have recently been completed by La Societe des Mines de Houille de Blanzy, at Montceau-les-Mines. These tests clearly demonstrated that their mine waste of not over 1/16″ size, which corresponds in analysis to low grade American anthracite or river coal, could be burned in pulverized form under boilers with a combined furnace and boiler efficiency, ranging from 82% to 85%, although the boiler used was not equipped with either superheater or economizer.

The fuel employed corresponded, after drying, to the following average analysis:

Percentage of ash	29.2%
" " volatile matter	11.2%
" " fixed carbon	59.1%
" " moisture	0.5%
B. t. u.'s per pound	10,728
Fusing temperature of ash from	2,120° F. to 2,228° F.

The installation for the test consisted of one water tube boiler, B. & W. type, having 2,368 sq. ft. of heating surface. The test consisted of an uninterrupted 30-day run of 704 hours. During this period the hourly evaporation for each 10 sq. ft. of heating surface was 30.19 lbs. of water per hour, which exceeded the 29 lb. guarantee.

Evaporation of from 36 to 45 lbs. of water per 10 sq. ft. was easily attained for periods of several hours at a time.

The average evaporation per pound of coal was 6¾ lbs. of water, which also well exceeded the guaranteed performance of [illegible].

During the first 12 days of the test, the best method of operation and regulation was determined, and once having been attained was maintained until the end without difficulty. The hourly evaporation per 10 sq. ft. of heating surface showed an average of 30 lbs. of steam, and the average evaporation per pound of fuel was 7.38 lbs. of steam, which corresponds to an over-all efficiency of 82% for furnace and boiler.

During periods of more than 48 hours, the evaporation per pound of fuel was maintained between 7.61 and 7.65, which is equivalent to an efficiency of 85%.

During the whole time of the test, the ash was extracted easily—partly in a state of dust and partly in a spongy and vitrified state. The smoke leaving the stack was light and of a clear color and caused no deposit of dust in the neighborhood or surroundings of the installation. After cooling off, the combustion chamber was found in good condition and ready to operate again without making any repairs whatever. Considering the high efficiency obtained, this speaks very highly for the installation of the combustion chamber.

Coal preparing and burning equipment consisted of one 5-roller pulverizer, one dryer; two powdered coal feed controllers and two low pressure burners at the combustion chamber with the necessary blowers for supplying the air, for carrying the coal from the powdered coal feeders into the burners.

The equipment for the powdered coal installation was manufactured in France along American lines by the Societe Quigley-France (Emploi des Combustibles Pulverises) with the assistance and guidance of Quigley Fuel System, Inc., 26 Cortlandt Street, New York, and their engineer resident with the Quigley-France Company.

SIZE OF MAGNET

(Continued from Page 30)

a given permeability, multiply the desired lines of force by the reluctance.

(d) Total flux is determined by the number of turns, supply volts, frequence, as follows:—

$$\text{Flux} = \frac{\text{voltage} \times 10^8}{4.44 \times \text{frequency} \times \text{turns}}.$$

From these rules you will be able to calculate the ampere turns required to develop the number of lines of force necessary to lift 5 lbs. From this you will in turn be able to judge whether you have enough space on your solenoid to accommodate the amount of wire.

In connection with A. C. solenoids, special provision must be made to prevent humming, side vibration, and sparking. Effect of low power factor must be considered.

FALL REPAIRS

Coal strikes make it more necessary than ever that you should overhaul your power plant in anticipation of cold weather and expensive fuel.

PLIBRICO jointless fire brick will give you a one-piece monolithic lining. Our book, "Modern Furnace Building," will show you how.

PYRO-HERMETIC Seal will make your boiler settings air-tight and stop all leaks. Water and Metal Feedwater treatments—Spencer Damper Regulator.

AMBEST metallic packing will take care of your packing troubles at minimum cost.

Beveridge Supply Co., Ltd.

628-630 St. Paul St. W.

YOUR POWER PLANT IS THE HEART OF YOUR BUSINESS

Ask For Your Copy

This book will tell you about

PLIBRICO JOINTLESS FURNACE LINING

Write for your copy to-day —L-74, on "Modern Furnace Building."

PLIBRICO makes baffles, side walls, bridge walls, and front and rear arches that are air and gas tight, that resist heat up to 3100° F., and that outlast laid-up fire brick many times.

PLIBRICO is delivered only in steel containers of distinctive appearance, as shown below.

DISTRIBUTORS:— Beveridge Supply Co., Ltd., Montreal, Que.; Shell Bar Boiler Supply Co., Ltd., Toronto, Ont. Evans, Coleman & Evans, Vancouver, B. C.; Winnipeg Supply & Fuel Co., Winnipeg, Man.; Gorman's, Ltd., Calgary, Alta.

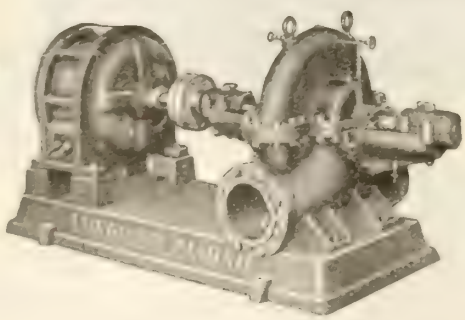
AMERICAN-MARSH PUMPS

Centrifugal and Direct Acting



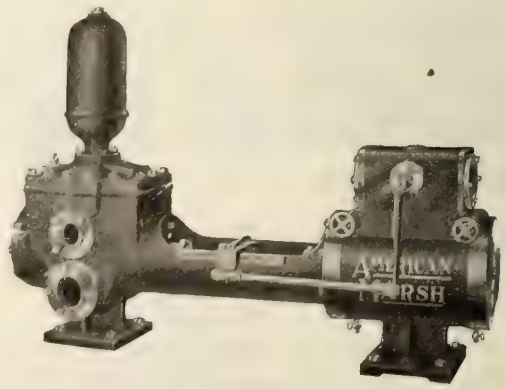
Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The Line includes :

Boiler Feed Pumps	Jet Condensers
Air Compressors	Vacuum Pumps
Deep Well Engines	Condensation Pumps
Centrifugal Pumps	Sump Pumps



May we send you our general Catalog?

When fire fingers pick at furnace linings

ONCE let the intense flame of modern boiler firing get its destructive grip on a weakness in the furnace lining and complete destruction soon follows.

Ordinary fire-clays that fuse and crumble out from between the brickwork weaken it by leaving edges and sides exposed. The brick becomes "heat soaked" and in turn fuses or spalls away. A costly shut-down for repairs or complete replacement results.

Johns-Manville Heat Treatment protects the fire-brick. Two classes of high temperature cements are used—an elastic binder for laying up the brick and an over-all coating which retards surface fusing and the adhesion of clinker. Heat Treated furnace linings outlast fire-clay construction because they are uniformly strong all over.

This brings a direct saving in repairs and a lower operating cost due to less frequent shut-downs. Send for booklet.

Save Your Waste Oil

The Anderson Oil Filter Type "A"

By collecting the waste oil in drip pans, properly located beneath the engine or machinery, and running it through the Anderson Filter you cut your oil bills in half. In the Anderson the used oil undergoes a cleansing, purifying treatment identical to that of the refiners. It comes from the Filter clean and pure, suitable for use on the finest bearings.

The Anderson is an economy too great for you to overlook. to-day for catalogue.

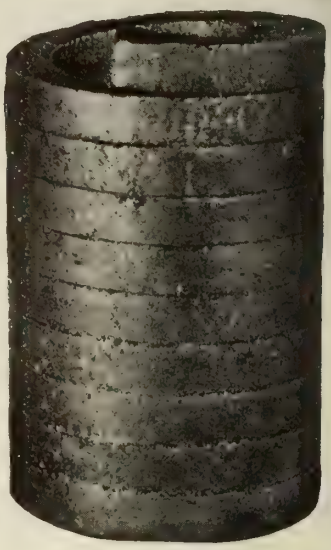
"JOHN CRANE"

Flexible All-Metallic Packing

Style 100

for temperatures up to 450 and rod speeds of 400 feet per minute.



Service

Spiral babbitt foil impregnated with purest flake graphite. Made in coils in all sizes for general use. Self lubricating, easily applied. A money saver because it lasts longer than fibre packings and runs with minimum of friction. Won't wear rods or plungers.

Try John Crane Packing NOW.

Our free illustrated text book on metallic packing explains superiority of application to every power plant service.

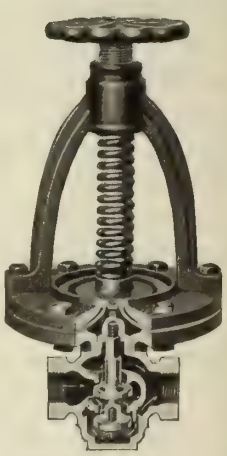
CURTIS ENGINEERING SPECIALTIES

Comprise a line of devices that have stood the test of years for the utmost in efficiency. They are built for dependable and enduring service. Scrupulous care in the selection of material and in construction, with adherence to the highest engineering standards, have won them a commanding position. The



CURTIS WATER-PRESSURE REGULATOR

will deliver water into service pipes at any desired pressure, regardless of any fluctuations of outside pressure.

Trouble with rust or clogging with sediment is prevented. Waste of water in domestic use by flying or spattering is avoided by the reduced pressure. This also prevents water hammer or concussion and prevents wear and tear on all packings and seats in valves and faucets, thus eliminating frequent plumbing bills. Adapted for use in pulp and paper mills, hotels, public buildings and dwelling houses. For ¾ in. to 2½ in. pipe, screwed. For 3 in. to 8 in. pipe flanged.

The Curtis Line of Steam Specialties contains many other notable devices. They are fully described in our No. 50 catalogue. Write for a copy.

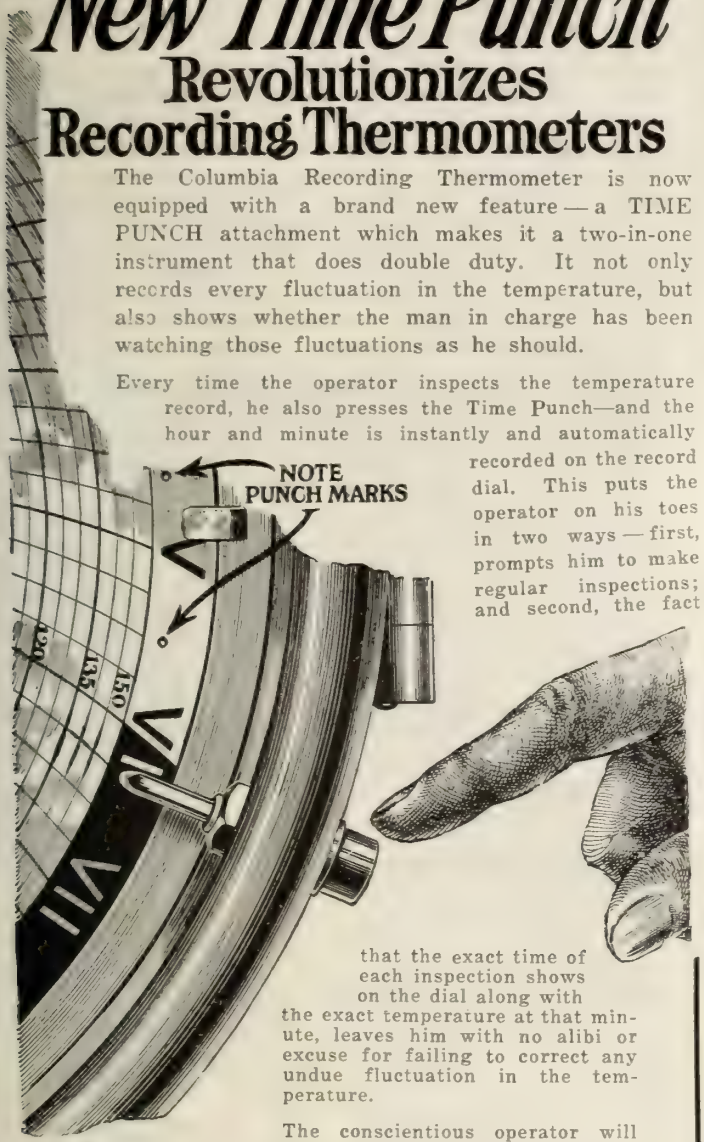
New Time Punch Revolutionizes Recording Thermometers

The Columbia Recording Thermometer is now equipped with a brand new feature — a TIME PUNCH attachment which makes it a two-in-one instrument that does double duty. It not only records every fluctuation in the temperature, but also shows whether the man in charge has been watching those fluctuations as he should.

Every time the operator inspects the temperature record, he also presses the Time Punch—and the hour and minute is instantly and automatically recorded on the record dial. This puts the operator on his toes in two ways — first, prompts him to make regular inspections; and second, the fact that the exact time of each inspection shows on the dial along with the exact temperature at that minute, leaves him with no alibi or excuse for failing to correct any undue fluctuation in the temperature.



The conscientious operator will take pride in having the proof of his dependability put on record; while the man who is inclined to be careless or forgetful will immediately brace up when he knows there is a constant check on him. The result in either case is bound to be a more uniform temperature—less spoilage and damage, greater efficiency, lower operating costs.

DE LAVAL OIL PURIFIERS

are the more economical and more efficient means of dehydrating transformer oil or purifying lubricating oil for either Diesels or turbines. Strong centrifugal force, made more effective by the De Laval system of strata distribution, effects so positive a removal of water and solid impurities that the efficiency of oil is indefinitely maintained or restored by the use of these centrifugals.

Write for Bulletin No. 105, which gives full information regarding De Laval Oil Purifiers.

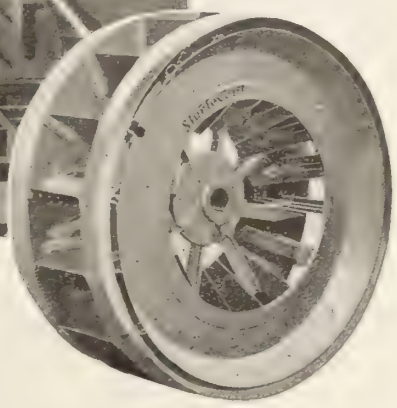
Installation in a Municipal Lighting Plant.



Rotating Member of the Cindervane.

The Cindervane Has Proved Itself

Actual tests showed that four requirements were necessary for catching cinders before they went up the stack to be distributed over the neighborhood. These were.

High efficiency in cinder elimination. Reasonable first cost.
Slight reduction in Temperature. Low Power Consumption.

Actual practice shows that the Sturtevant Cindervane possesses all these necessary requirements to a considerable degree. In addition, a highly efficient induced draft is afforded.

It is the only unit made that serves this double purpose. The Cindervane eliminates cinders as satisfactorily as it gives an induced draft.

Every power plant is interested in abating the cinder nuisance. Before discussing your proposition with our engineers we would like you to see a Cindervane under actual working conditions.

Send us your name so that we can forward the address of the installation nearest you.

Payroll cut from 49 to 12 men; now burns fewer tons of cheaper coal

WHEN the eighteen 350 h.p. boilers installed in the power plant of a big steel and wire plant (name on request) were hand fired the boiler room payroll included 25 men days and 24 men nights. Since the boilers have been equipped with Jones "A-C" Stokers of three retorts each, less than one-fourth the former crew is necessary. Now 7 men days and 5 men nights are sufficient. Less fuel is burned than when the plant was hand fired and the Jones "A-C" Stokers have enabled the plant to change from $7.00 to $4.00 coal—cheaper coal and less of it.

This illustration of the savings made at this prominent plant proves the contention that "Jones Stokers pay for themselves—then pay dividends." And they pay dividends on a far greater scale because maintenance is so low that savings are practically net. The extreme simplicity of the Jones "A-C" permits rugged construction. Each retort is a simple, independent unit with only one moving part in the furnace — and that buried deep in the green coal.

Write for the Jones "A-C" catalog. Learn the story of greater savings with extremely low maintenance.

Power House advertisers are at your service. Many engineers have been enabled to qualify for better positions, have been instrumental in securing the installation of more efficient equipment, have been of exceptional service to the firm they are engaged by, **because** of their superior knowledge of equipment, which knowledge was largely attained by being conversant with the latest advertised equipment, found in **Power House.**

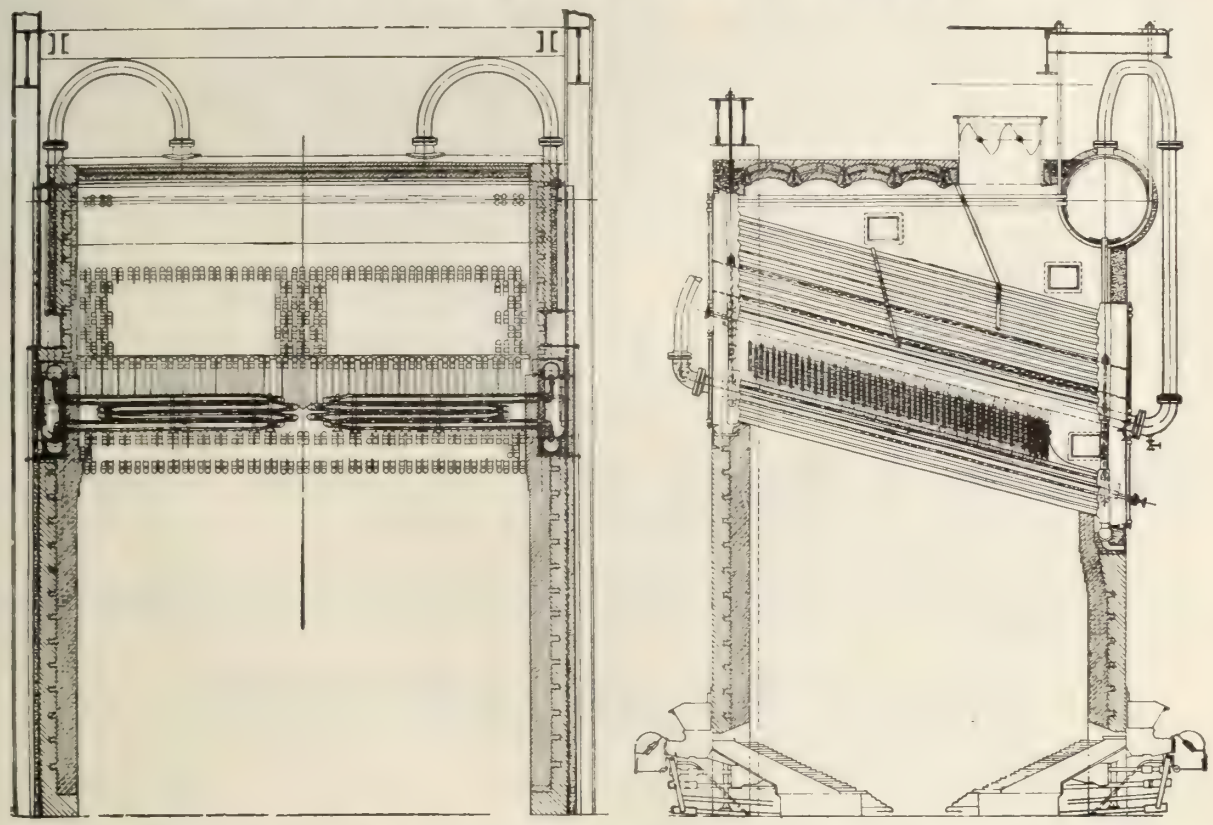
ELESCO

SUPERHEATERS



An Important Advance in Superheater Engineering

The important features embodied in the design of the ELESCO Superheaters in the 12-1890 H.P. boilers at the Hell Gate Plant of the United Electric Light and Power Company, New York City, may be briefly summarized:

200° F. superheat at a low first cost.
Safe gas temperature zone location.
Minimum fluctuation in steam temperature at different boiler ratings.
High steam velocities with minimum pressure drop.
Equal distribution of steam through the superheater at all ratings.
Breaking up of possible slugs of water.
Fewest possible number of steam tight joints.
Elimination of baffle joints between superheater and boiler.

The performance of the ELESCO Superheaters in this plant fulfills the exacting requirements of a central station of large capacity.

THE SUPERHEATER CO., LIMITED

Transportation Building - MONTREAL

MADE IN CANADA

Better Results with Cheaper Fuel

With the National Hand Fired Stoker--

The heavy labor of firing is eliminated and low grade labor with very little training can get results all the time, day in and day out, that experienced stokers can only get part of the time. Any grade of fuel can be used—smoke is eliminated with all grades of coal—no fuel in the combustion chambers—no ashes in the flues—increased boiler capacity—and much lower labor cost are National advantages. The banks of Pushers, operated by rods from the front of the furnace keep the fuel moving downward until the dump plates are reached—insuring just about PERFECT COMBUSTION and a degree of efficiency and economy in your Boiler room that will delight you.

The National Hand Fired Stoker is applicable to old or new installations. We build it in St. Catharines. Let us send you full particulars and prices.

"The Buyers' Guide"

This familiar trade-mark is a reliable, trustworthy guide for buyers of belting. By it you may instantly identify "P. M. S", the belting that has established an enviable record for efficiency. "P. M. S" gives superior adhesion to pulleys, even pliability, great strength, and resists the effects of heat, cold and moisture. Its comparatively low first cost makes it particularly worthwhile trying out in your plant.

MORRISON

STEAM GOODS

The Morrison Automatic Injector

Morrison "Standard"
specially built and recommended for working pressures up to 150 lbs. per square inch.

THE knowledge gained from more than 50 years' successful experience in the manufacture of steam goods is exemplified in the Morrison Automatic Injector.

It has been in general use as an "All-Round" Boiler Feeder for over 25 years and has become one of the standard machines recognized by the trade for efficient and durable service. It acts as a Boiler Feeder under all the varying conditions of pressure and temperature limits. Our High Pressure Injector, in fact, will operate under a wider range of boiler pressures than any other device we know of; viz, from 20 lbs. to 220 lbs. per square inch.

Special Styles

By reason of lack of space or because the user wishes to have the over-flow of the injector in a certain position, special style Morrison Injectors are made with connections to meet requirements. They are made in all sizes in both the Standard and High Pressure types shown here.

Full particulars of these and the other Morrison products will be found in the Morrison catalog. Send for a copy.

Morrison "High Pressure"
adaptable for satisfactory service on working pressures up to 220 lbs. per square inch.

Special Style
Left and Right. Standard and High Pressure.

Here's A New Jenkins Valve

Spindles of this new Jenkins Valve are made of Monel Metal. Hand levers are malleable iron lacquered green.

Ideally suited to every service where a dependable, quick opening valve is needed.

JENKINS
Rapid Action Valves

save time and labor in Laundries, Creameries, Shower Baths, Steam Pressing Tables and various other devices.

They open with one quarter pull of lever, stay open automatically and close with a slight pull of lever.

Valves are made of bronze and are fitted with Jenkins Renewable Composition Discs.

May we send you descriptive literature describing this Rapid Action Valve in detail?

MUELLER

It's made of high grade metal throughout.
Has large and correctly made packing gland with specially made packing.
Inside threaded bonnet gives greater strength to body and prevents any possible corrosion.
Large hexagon strengthens valve and gives a "non-slip" wrench grip.
Valve can easily be repacked under pressure because the shoulder on stem, seats effectively in the bonnet when valve is full open.
The Disc Holder can easily be removed in a few seconds for insertion of new disc.
Mueller Composition Discs are designed and manufactured to withstand high pressure and the action of high temperatures.
Full length tapered threads.
Barrel type of body is used.
Full sized opening through valve body in Mueller Valves.
Mueller Valves will help keep expenses down to a minimum by giving you better service on your steam lines.

DURABLA

A Sign of Good Belting

Remember the "P. M. S" trade mark. Next time you order belting think of "P. M. S" and test it out under the severest conditions you have in your plant—as long as the test is a fair one. You'll always be glad you decided to use

"P. M. S"

It excels in adhesion to the pulleys, even pliability, strength, and its marvellous resistance to the action of heat, cold or moisture. It has a wide range of usefulness and its comparatively low first cost is an additional good reason for its adoption in your plant.

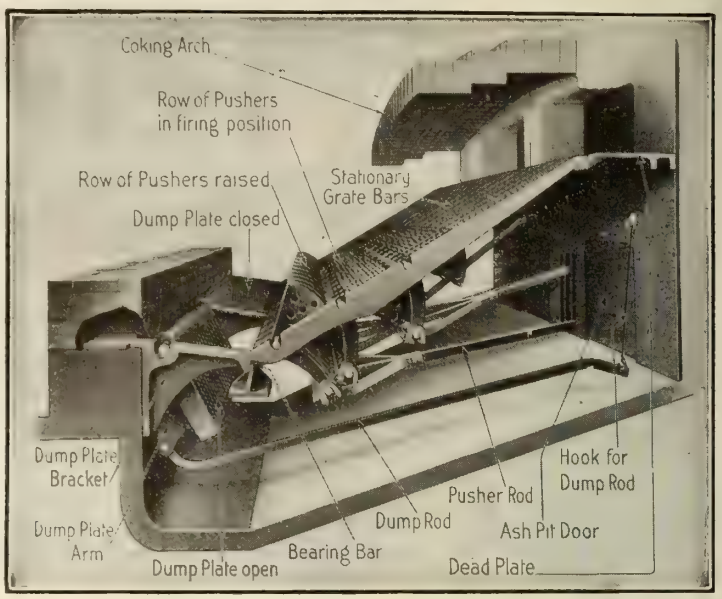
Better Results with Cheaper Fuel

With the National Hand Fired Stoker--

The heavy labor of firing is eliminated and low grade labor with very little training can get results all the time, day in and day out, that experienced stokers can only get part of the time. Any grade of fuel can be used—smoke is eliminated with all grades of coal—no fuel in the combustion chambers—no ashes in the flues—increased boiler capacity—and much lower labor cost are National advantages. The banks of Pushers, operated by rods from the front of the furnace keep the fuel moving downward until the dump plates are reached—insuring just about PERFECT COMBUSTION and a degree of efficiency and economy in your Boiler room that will delight you.

The National Hand Fired Stoker is applicable to old or new installations. We build it in St. Catharines. Let us send you full particulars and prices.



Engineering & Machine Works of Canada, Limited

Eastern Sales Offices : Hall Machinery Co., Sherbrooke, and Birks Bldg., Montreal

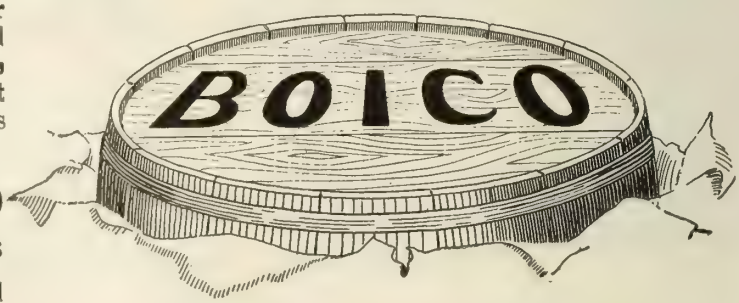
The Safe and Certain Boiler Cleanser

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.** BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.



Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

Renewable "VALVE NICKEL" Disc and Seat

LUNKENHEIMER

"Renewo" Valves are the climax in the evolution of valve design from the old style soft seat valve for low pressures to the present day high pressure and temperature valve.

The "Valve-Nickel" **seat ring** and **disc** in "Renewo" Valves have unusual wear resisting qualities under extreme operating conditions. When wear does occur the seating surfaces can be reground or the **seat ring** and **disc can be renewed.** With all other parts made of high-grade bronze, formulated for the duty each part performs, the life of the valves is prolonged indefinitely.

"Renewo-equipped" means permanence, and represents an investment unparalleled in point of value to the purchaser seeking the highest degree of efficiency and economy in valve **service.**

Booklet 535-DC lists and describes the full range of types, sizes and weights of patterns available. Write for a copy.

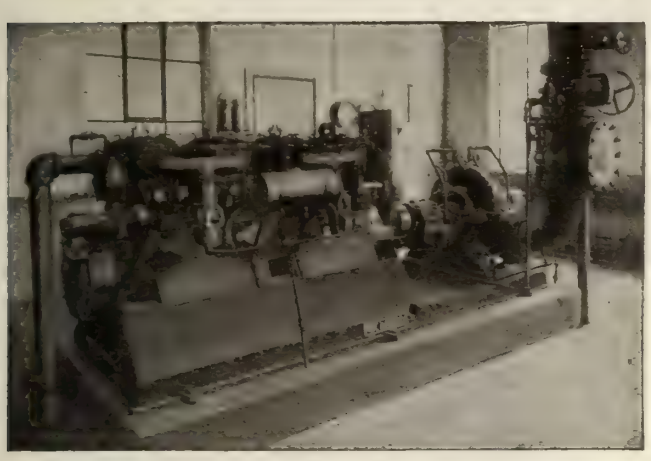
Pumping Without Steam



THE accompanying photograph shows a De Laval six-inch two-stage centrifugal pump, driven by an 8-cylinder gasoline engine as installed at Pembroke, Ont. The unit has a capacity of 960 gal. per min. against 349 ft. head at 1,400 r.p.m. This combination offers the maximum of simplicity and reliability where water is wanted in large quantities and steam or electric power is not available. Units of this type are built for direct connection to engines using gasoline, natural and artificial gas and oil. The gearing, plungers, packings and valves of reciprocating engines are eliminated and the absence of heavy friction at starting is a great advantage where internal combustion engines must be started by hand.

If you are interested in centrifugal pumps for any situation, write for our new Centrifugal Pump Catalog B-100.

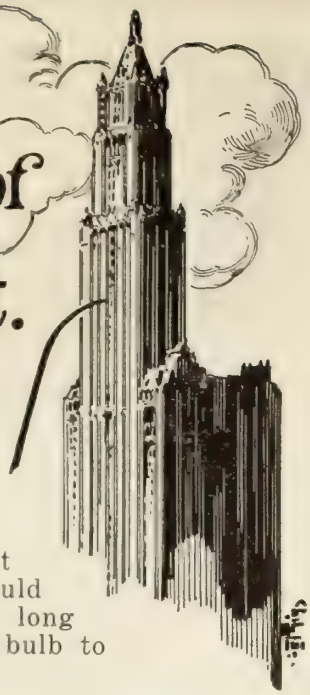
Taking Temperature at a Distance of 500 ft.



Have you ever wanted to install a thermometer dial a long distance from the point where the actual temperature is taken and found that you could not get a thermometer that would operate accurately at a long enough distance from the bulb to meet your requirements?

It is now possible, with the Indica ing Thermometer Sarco, to maintain a *practical and accurate* surveillance over temperatures in various heat-treat processes—at distances up to 500 feet.

Neither the transmission tube filling, nor the thermometer itself, are in the least affected by temperatures higher or lower than that of the bulb. The dial always indicates the *true bulb temperature*, regardless of its own temperature or the temperature of the rooms through which the connecting tubing passes.

Manufactured by thermometer experts in our own laboratories, under the well-known Fournier patents. Hundreds of thousands of Thermometers of this type have been in successful use for more than ten years.

We'll ship you a Sarco with the distinct understanding that it *must give entire satisfaction*, otherwise you may return it within 30 days and the trial will cost you nothing.

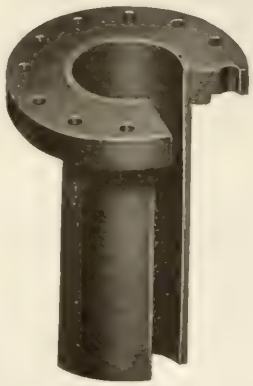
P⊕H FLANGED PIPE JOINTS



SCREWED

P.H. LAP

P⊕H LAP FLANGES, for any service, have proven to be the best yet designed, and they have many advantages over other styles. The pipe is not weakened by cutting into the wall as when using screwed flanges. The gasket bears on the face of the lap and absolutely prevents leakage through the bore of the flange. The hub of the flange is bored slightly larger than the outside diameter of the pipe so that the flange will swivel readily and accommodate itself to any slight variation in the position of the bolt holes, an advantage which is obvious to the fitter and eliminates torsional strains in attaching.

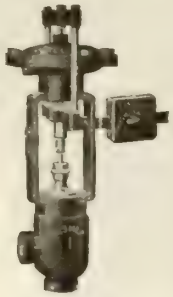
FISHER
TRADE MARK REGISTERED



Merit Wins

A good man always comes to the fore. When anybody or anything is better than average the world soon knows it.

This universal truth again reveals itself in the popularity of Fisher Steam Specialties. What engineer in all this land does not know the Fisher line?

Again it is proven, merit wins.

Fisher Vacuum Pump Governor

(Type 8)

a prominent member of the Fisher line, is used in the vacuum heating systems of such well-known buildings as the Canadian Pacific Bldg., Toronto, Canada; Woolworth Bldg., New York City; North American Bldg., Chicago, Ill.; and many others. Judge it by the company it keeps.

Fisher Vacuum Pump Governor is super-sensitive. The extra-large diaphragm makes it so. As you see in the illustration it has lever and weight control. This control is positive—never changing—and we can guarantee an absolutely accurate regulation of vacuum.

This governor is made of the same high-grade materials found in other Fisher Steam Specialties. Type of construction allows us to furnish it with either globe or angle bodies. This is a convenience immediately recognized.

Write for book, "POWER PLANT SPECIALTIES," which tells all about this and other Fisher Specialties.

The Fisher Governor Company

Agencies in all principal cities

A simple, inexpensive self-cleaning stoker

THE Jones "Standard Side Dump" Stoker meets the demand of Canadian plants for inexpensive, self cleaning stoker that saves fuel and labor.

The same retort, hopper, steam cylinder and ram that have proven so successful with the Jones "Standard" Stoker are used. Instead of the hand cleaned dead plates, sloping combustion grates and hand operated dump plates are used. Successive strokes of the steam driven ram move the coal rearward and upward through the stoker retort (shown above) as it undergoes the different stages of volatilization, coking and combustion. The ash is deposited on the side dump plates, and is dropped at intervals into the ash pit below. Only a slight, inexpensive excavation is necessary for the ash pits; Jones "Standard Side Dump" Stokers may easily and cheaply be installed under existing boilers.

High capacity, maximum efficiency, smokeless operation, rugged construction, low maintenance through lack of moving parts in fire, automatic control of fuel and air, and all other advantages of other Jones types are found in the "Standard Side Dump" Stoker. *Ask for Bulletins.*

On existing installations of Jones "Standard" Stokers it is possible to apply at very small cost the side dump attachments. *Write for folder.*

HEATING SERVICE
(Made in Canada)

DUNHAM REDUCING PRESSURE VALVES

The Dunham Line of Reducing Pressure Valves is the result of many years' experience in the manufacture of steam-handling specialties. They are worthy additions to the Dunham Line.

Dunham Reducing Pressure Valves are applicable to a wide range of initial pressures of steam, air, water, etc. They will reduce to the desired low pressure in one step, without chattering and are very sensitive in meeting sudden demands. The low pressure is evenly maintained, even though there be considerable variation on the high pressure side of the valve.

Regulation is by a lever and weight which may be set at any low pressure. Each instrument has a double balanced inner valve and seats of special phosphor bronze.

Full particulars will be sent upon request

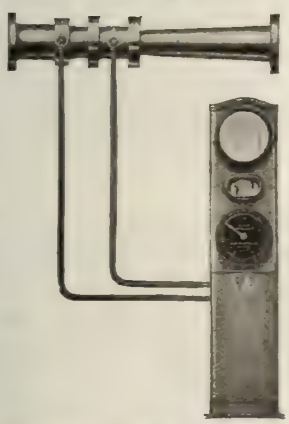
177 Delorimier Avenue - Montreal, Que.

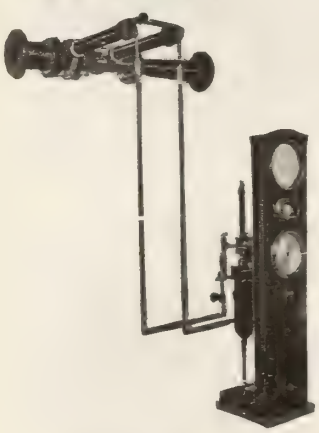
Bailey Boiler Meter
Type D-25—Class 56

THE VENTURI METER WILL TELL YOU



Venturi Boiler Feed Water Meter

1. How many pounds of water are evaporated for each pound of coal burned.
2. Which boilers are efficient and which need cleaning or repairs.
3. When a boiler can be cut out or another boiler should be put in service.
4. Whether or not the water tender is doing his work well.
5. Which kind and grade of coal is most economical for your boiler plant to use.
6. How much steam is used in the engine room.
7. How much steam is used for manufacturing processes.
8. How much steam is supplied for heating.
9. How much condensation is returned to the boilers.
10. How much circulating water is used by the condensers.



Venturi Steam Meter

Is not knowledge of these things vital for efficient power plant operation? The Venturi Meter is giving this information every day in thousands of power plants throughout the United States and Canada. Our accumulated experience in this field is at your disposal. Shall we send you further details?

REES RoTURBo CENTRIFUGAL PUMPS

REES RoTURBo single and Multi-stage centrifugal Pumps give high and permanent efficiency over a wide range of duties and being self-regulating insure the prime mover against overloading.

The low water velocity through all passages results in almost complete freedom from wear, even when pumping gritty water.

Owing to these and other important features more than 200 Rees Pumps have been installed in Canada during the last 3 years.

A few of them are shown herewith.

The Cause of Clinkers in Hand Firing

One of the Most Troublesome Things Found in Hand-firing Practice is the Clinker—This Article Tells How the Formation of Clinker May be Prevented by Proper Methods

By M. BARRY WATSON

Director of Engineering, Toronto Central Technical School

CLINKERS may form over the whole grate area under a boiler forming an effective air stop, which must be broken up in order to let sufficient air through to the fires, and must be removed at the first opportunity; or they may be more noticeable as "growing" to the walls of the setting.

The most noticeable effect of clinkers is that they restrict the free flow of air through the fire, and by thus cutting down the amount of fuel that can be burned on the grate they reduce the boiler capacity. They have other evil effects such as the burning away of the grate bars and the disintegration of the brickwork.

Engineers and firemen in charge of hand fired boilers are generally more concerned with clinker formation than those having automatic or mechanical stokers under their care; although the behaviour of fires in the case of a sprinkling type of stoker is somewhat akin to conditions under hand firing. In practically all types of mechanical stokers that are self cleaning, clinkers are formed, but are of little trouble, because the constant agitation of the grates or fuel bed keeps them broken up so that the air can pass through. In the Murphy furnace there is a clinker grinder provided to break up clinkers that form and pass them through with the smaller ashes. In the travelling grate type of stoker, if clinkers form badly, the chain grate may be slackened off sufficiently that it travels over its supporting rolls in a snake-like motion, allowing the clinkers to break of their own weight as their points of support change, and allowing plenty of air to pass through, the clinkers being finally disposed of by being carried over the rear end of the grate to the ash pit or the dumping plate. In the travelling grate type of stoker, however, trouble may be experienced by clinkers growing to the side walls of the setting. In the various underfeed types of stokers the agitation of the fuel bed by the grates or push rods, etc., keeps the clinkers broken up until they roll down to the sides or back of the fire where they are removed either by hand, by a dump-plate or a clinker grinder. In most of these types there is little trouble with clinkers "growing" to the side walls.

Certain kinds of coal can not be burned under any conditions without the formation of large quantities of clinkers on account of certain fusible impurities contained in or mixed with the coal which melt when heated, and on cooling form a hard slag or clinker which seems to combine with the material of the grate bars, etc., in some cases and becoming almost impossible to remove. Fortunately, however, such kinds of coal are uncommon, and the average run of coal can under certain conditions be fired with but little trouble from clinkers.

Clinkers can be formed in burning any kind of coal under certain conditions, which conditions are more or less known to most engineers. The clinker is composed of ash which when released from its combination with combustible matter is raised to a temperature sufficiently high to melt it or at least to make it soft and sticky. Most of the ash formed is in this condition when first liberated. If this ash upon formation drops down near the grate where it is cooled by the incoming air it solidifies in small particles and most of it falls through the grate to the ash pit. If on the other hand it falls from one to another of the layers of burning fuel beneath it, it will gather up more and more of this soft sticky ash forming large clinkers or even forming a more or less continuous blanket somewhat above the grate. As soon as the greater part of the combustible matter is burned away from beneath it, this mass will solidify, preventing the free flow of air to the fuel above. This blanket must be broken up and the pieces removed when possible, making more work for the fireman.

The walls of a furnace are always somewhat cooler than the burning fuel. Thus if any of this molten or sticky ash comes in contact with these walls it at once sticks and solidifies. This small layer of clinker now acts as the wall and collects more and more of the sticky ash, until large clinkers have "grown" to the side and bridge walls. These clinkers may extend several inches from the walls over the grate, effectively shutting off the air supply that should come through the part of the grate covered. Thus the effective size of the grate and the power capacity of the boiler are reduced to a very appreciable extent. These clinkers are sometimes so hard and stick so tightly to the walls that the brickwork is damaged in dislodging them. It is generally found that these clinkers "grow" to the walls between about three and ten inches above the grates depending on the thickness of the fire. They seldom, however, extend closer than three inches to the grate.

It would appear from the above that to prevent the formation of clinkers we must attack the trouble at its source and endeavor to prevent the ash as it forms from coming in contact with other particles of ash, or the walls of the setting, until it has become sufficiently cool that it is no longer sticky. There are, however, other condititions which can help or hinder the formation of clinkers, such as the temperature of the fire at the point of ash formation and the composition of the furnace gases at that point.

Fusing Point of Ash

It has been found by Mr. Kreisinger* and others that the temperature of the fuel under hand fired boilers varies between 1,800 and 2,700 degrees Fahrenheit.

With low rates of combustion, i. e. 20 to 30 lbs. coal per square foot of grate surface per hour, the temperature of the fire is highest at about 2 to 4 inches above the grate, where it is around 2,400 deg. F., while it is as low as 1,800 at 7 to 10 inches above the grate depending on the thickness of the fire.

With high combustion rates, i. e. 100 to 125 lbs. coal per sq. ft. grate per hour,

*U. S. Bureau of Mines, Technical Paper No. 137.

the high temperature of about 2,600 to 2,700 deg. F., is maintained from about 4 to 8 inches above the grate.

Messrs. Fieldner and Hall of the United States Bureau of Mines have found by experiment that the melting point of ash from ordinary soft coal, apart from being dependent on its own chemical composition, varies according to the kind of atmosphere in which it is heated. †

The general conclusions reached from the result of the above mentioned experiments and tests are that when ash is heated in an atmosphere containing plenty of free oxygen, its melting point varies with the composition of the coal from about 2,500 to 2,650 deg. F., whereas if heated in a reducing atmosphere or atmosphere lacking in free oxygen, the melting point averages about 100 degrees lower than the above.

From a consideration of the temperatures of fires and the melting points of ash as found above, it would appear that with low rates of combustion, where the temperature of the fire is little, if any, over 2,400 deg. F., there would be little trouble experienced with clinkers. This conclusion is borne out in practice, as everyone knows that very few clinkers form when very light fires are being carried.

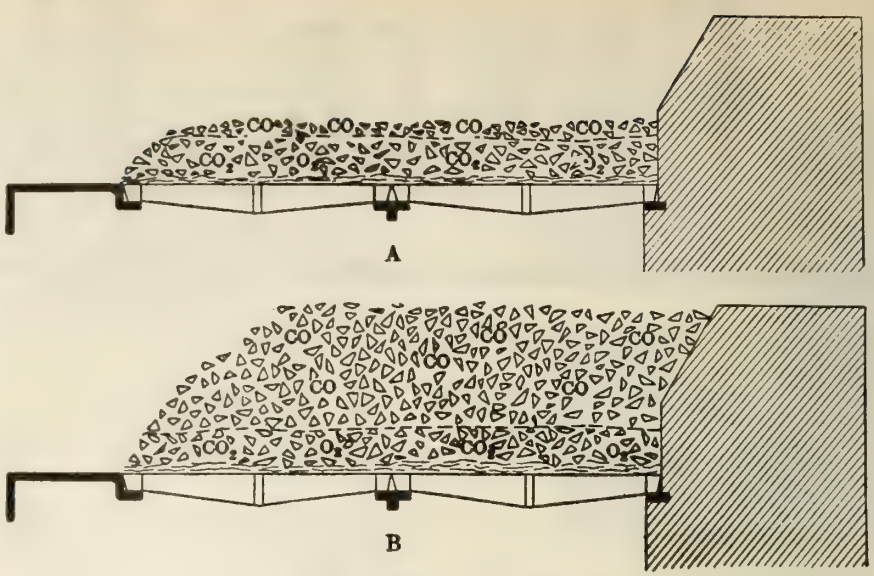
With high rates of combustion, the lower three or four inches of the fuel bed are apparently kept cooler than that above by the rush of cold air entering through the grates. This explains the tendency for clinkers on the side walls not to form close to the grate. Above the three or four inch level the temperature of the fire is probably higher than the melting point of the ash, and with thick fires this plastic ash collects in large sized clinkers before it gets down to the cooler layers. With thin fires, say [illegible] inch, most of the ash is formed in the lower layers of the fire because only the gases and oils are being distilled off and burned during the time that the fresh fuel is on the top of the fire, therefore most of the ash will drop off from the lumps of coke in the cooler layer of the fire and little trouble will occur from clinker formation.

With medium combustion rates it is likely that the fire temperature is just around the melting point of the ash, and it is under these conditions that it is of importance to so control the quality of the gases in the fire that the ash will have as high melting point as possible, so it will be less likely to fuse into large clinkers.

Thick Fires a Menace

Thick fires are a more troublesome source of clinkering than all other causes combined. In the case of a fire only three to five inches thick, the flow of air keeps the grate bars and the lower layers of the fire, where most of the ash is separated out from the coal, comparatively cool so that the ash remains in small particles and easily falls through the grates. If a thick fuel bed is maintained the resistance to the flow of air is increased and much less air passes through the fuel bed, necessitating the admission of more air above the fire to ensure good combustion, thus the grate bars and the lower layers of the fire are not kept as cool as with a thin fire, and may rise high enough that practically all the ash formed will collect in large clinkers instead of dropping through the grate bars. Secondly, in the case of thick fires, the ashes which form several inches above the grate, which they are bound to do because the fire is so thick, can not fall to the cool layers of burning fuel, where they gather more sticky ash and eventually form large masses which form solid clinkers upon reaching the cooler layers near the grate. Thirdly on account of the smaller quantity of air passing through a thick fire, all the oxygen is burned out of the air in the first few inches of the fire bed and above that we find a reducing atmosphere, which as has been shown previously lowers the melting point of the ashes, tending to form more clinkers than would be otherwise formed at medium fire temperatures.

† U. S. Bureau of Mines Technical Paper No. 80.



Two Conditions of Fire Bed.

In order to illustrate the above conditions, the following extract is taken from the United States Bureau of Mines, Technical Paper No. 80.

"Suppose that in two boilers, A and B, exactly similar in design and size, coal is burned at the same rate, the total air supply being 17 pounds per pound of carbon in the coal, but in boiler A the fuel bed is 5 inches thick and in boiler B 10 inches thick. The low resistance of the 5 inch fuel bed in A permits about 12.2 pounds of the 17 pounds of air used to burn one pound of carbon to enter through the grate, and only 4.8 pounds are admitted over the fuel bed. On the other hand, the high resistance of the 10 inch fuel bed in B allows only 7.9 pounds of air to enter through the grate, so that 9.1 pounds must be introduced over the fuel bed.

"The compositions of the gases rising from the fuel beds in the two furnaces are about as follows:

Boiler No.	Carbon Dioxide (CO_2)	Oxygen (O_2)	Carbon Monoxide (CO)	Nitrogen (N_2)	Pounds of Air per Pound of Carbon
A—	13.0	3.0	6.0	81.	12.2
B—	5.0	1.0	22.0	83.	7.9

"The composition at the end of the combustion space after all of the 17 pounds of air has been introduced and combustion is completed, is about: CO_2, 14.0 per cent.; O_2, 6.0 per cent.; CO, 0 per cent.; N_2, 80 per cent.

"It is easy to see that 12.2 pounds of air flowing through the grate of boiler A absorbs more heat from the layer of ashes and thus keeps them cooler than the 7.9 pounds of air flowing through the grate boiler B. Consequently the ashes in B will become hotter than the ashes in A, and the danger of bad clinker will be greater.

"The fusion temperature of the ash is lowered by the reducing atmosphere surrounding the upper layer of ashes. In a thick fuel bed the ash becomes mixed with burning coal to a greater height than in a thin one, and at the same time, on account of the lower velocity of the gases the reducing zone is nearer the grate than in a thin fuel bed. In fact, in thin fires the reducing zone may be limited to the top inch or two of the fuel bed, where the bits of ash are comparatively few and far apart, and can not melt together even if they are heated to the fusion point. The distribution of ash and the probable oxidizing and reducing zones are illustrated in Figures A and B. The reducing zone is marked by CO; the oxidizing zone is marked by CO_2 and O_2. The particles of ash are represented by elongated dots. The line between the ashes and the burning coal is more marked in the thin fire than in the thick one.

"Two cases of clinker caused by a thick fuel bed are given below:

"At a plant containing two 250 horsepower boilers complaint was made of one or two shutdowns daily on account of clinker. The writer was sent to investigate the cause of this trouble and found on visiting the plant, at about 9 o'clock in the morning, that the fires were 12 to 16 inches thick, were badly clinkered, and the steam pressure was slowly dropping. The fireman stated that he had started his daily shift with a clean fire at about 5.30 a. m., and that the clinker had accumulated since then. It was evident that the fires could not be run until noon and a shutdown was inevitable; consequently, firing was stopped altogether. The fires were allowed to burn down as much as possible and then were thoroughly cleaned. Cleaning was difficult, as the clinker adhered to the grate, side walls and the bridge wall. It took over an hour to clean the two furnaces. After cleaning, fires about five inches thick were carried and the steam pressure was kept easily near the blowing off point until 9 p. m. without further cleanings. At this time the fires were cleaned. The refuse found on the grate consisted mostly of free pieces of ashes and was easily removed with a hoe. No slice bar was used. This plant could run easily from morning till evening without the fires being cleaned.

"At another small plant having two horizontal tubular boilers of 150 horse power each, trouble from clinker was reported. A black matter was said to run into the grate and choke the air supply. On visiting the plant the writer found that the fireman carried a very heavy fire, 14 to 18 inches thick. The fuel bed extended to the fire door, covering the deadplate completely and nearly filling the firing door opening, so that firing was difficult. The fire-door arches and lining were badly burned, and the cast iron furnace front was cracked and warped in many places, from the fire being kept inside the firing door. The molten ash was running through the grate as a black, sticky substance, which hardened below the grate and formed 'icicles.'

"The cleaning of this fire was difficult on account of the clinker being fused into the grate. After the fires were cleaned a light fuel bed about five inches was carried, and to the surprise of the fireman the load was carried on one boiler. After carrying a light fuel bed for six or seven hours the fires could be cleaned without the use of a slice bar. After the change to light fuel bed this plant had no trouble from clinker."

Don't Disturb Fires

Next to too thick fires, the most common cause of clinkering is too much stirring of the fires. Most soft coal, especially if containing much slack, will, if fired thickly, fuse into a sticky mass due to the distillation of the tar and oils contained in it, leaving an almost solid blanket of sticky coke over the fire. To remedy this condition many firemen run the slice bar under the fire and pry up on it to break the crust to let the air through. In doing this some of the ashes and small clinkers from the cooler area at the bottom of the fire are lifted into the upper and hotter parts of the fire, where, there being a reducing atmosphere, they are sure to melt forming troublesome clinkers. Ash may even be lifted in the fire bed by the careless handling of the rake with the inevitable result of more clinkers.

Burning fuel in the ash pit is another fruitful cause of clinkers, and may also cause overheating and warping of the grate bars. Of course fuel is never purposely placed in the ash pit to be burned, but it is generally the result of poor firing methods. Some firemen have tried to use the "coking and spreading" method of firing, by which the green fuel is placed on the front portion of the grate where it is coked by the heat of the rest of the fire and the setting, and then spreading it after it has become fused into large lumps of coke, over the back portion of the grates, with free-burning or non-coking coal. In the process of spreading the free-burning coal, which remains in small lumps, over the back portion of the grate, considerable quantities of this coal may drop through the grates into the ash pit. Fuel may also get into the ash pit by the fireman allowing his fire to burn in holes and trying to fill up the holes with green fuel, part of which drops through the grate. Fresh coal or coke in the ash pit will be ignited by the radiant heat of the fire above the grates and will cause a fire hot enough to make the grate bars red hot and melt any ash lying there. This of course is assisted by the incoming air being heated up by the fire under the grate and thus being unable to keep the grate bars and lower layers of ashes cool. Molten ash in this position runs into the grates shutting off the air supply, thus cutting down the oxygen and producing a reducing atmosphere at the grates making conditions worse and worse. This clinker when the grate bars are red hot seems to corrode and combine with the iron of the bars thus weakening them. At the same time the bars are likely to warp badly and soon become useless.

Attempting to regulate the rate of combustion by opening and closing the ash pit doors may at times be a fruitful source of clinkers, as well as being wasteful of fuel as far as economical combustion is concerned. If the ash pit doors are closed when the fire is hot, the flow of air to keep the grates cool is at once cut off and the lower layers of ash are fused into clinkers by the heat of the fire above. At the same time the cutting off of the air causes a reducing atmosphere on account of the supply of oxygen being lessened, which lowers the melting point of the ash so that clinkers are more likely to form.

Highly preheated air supplied to the ash pit will also tend to cause clinkering, but the preheating of air is very unusual in hand fired boilers.

The remedies for clinkers formed by any or all of the above mentioned causes or conditions may be summarized as follows:

1. Keep the fire bed thin, not over six inches at the outside.

2. Do not level the fuel bed with a rake but place more fuel on the thin spot. Above all do not disturb the fuel bed with the slice bar.

3. Fire small charges of fuel at one time. This is especially important if the coal contains much slack or contains much tarry matter, in order to prevent the formation of thick crusts which can not easily be broken through from the top by dropping the rake on it. Firing lightly and often will incidentally increase the efficiency of the furnace and will reduce the smoke escaping. This is about the only respect in which the sprinkling type of stoker is superior to hand firing.

4. Avoid burning coal in the ash pit. If holes should develop in the fire it is permissible to use the rake to spread a little burning fuel on the bare spots before covering with green fuel, but in doing so, lumps which will not drop through the grates should be used if possible. If fire in the ash pit can not be prevented in this way, keep a small quantity of water in the ash pit, the evaporation of which will absorb much of the heat and prevent the coal burning. If the ash pit will not hold water, a little exhaust steam can be fed to the ash pit with good effect.

5. Do not try to control the rate of combustion by means of the ash pit doors, but always use the chimney damper. This keeps an oxidizing atmosphere in the fire, keeps the grate cooler, as well as tending toward more efficient combustion.

If all the above precautions are taken and bad clinkering continues, a little crushed limestone, walnut size, thrown on the fire when starting from a bank, or after cleaning, will help, but it is very seldom that this will be found necessary.

BULLETINS

The A. W. Cadman Manufacturing Co., Pittsburgh, have recently issued two bulletins, entitled respectively "Bearings and Bearing Metals," and "Cadman Metals." The first named which is known as Engineering Bulletin M-2, is a semi-technical treatise on bearing metals in general, including a short history of their origin, the requirements of a successful bearing metal, and friction in bearings. Some useful charts are included, as well as illustrations. Permissible bearing pressures and the heating effect on bearings are also treated.

The bulletin on "Cadman Metals" is known as Engineering Bulletin No. 1, and follows the same general lines as the first, excepting that the metals treated are those manufactured particularly by the firm itself. It is well illustrated, micro-photographs of different kinds of metal made by the firm being shown.

Principles of Design of Air Compressors

The Conclusion of This Article, the First Part of Which Appeared in the Issue of September 5th, Deals With Turbo Compressors and Their Characteristics

By WILLIAM REAVELL
Read before the Institute of Mechanical Engineers

TURBO-compressors.—Consequently for large volumes, the turbo-compressor, in connection with which Professor Rateaus' pioneer work has already been noted by the author is coming into increasing use. The evolution of the rotary compressor has been a very rapid one, and to-day the design and construction of this type has reached a fairly recognized standard practice.

A few years ago makers regarded a peripheral velocity of the rotor of about 500 ft. per sec. as a maximum permissible limit, but the present-day tendency aims at the adoption of higher speeds, which are rendered possible by the use of modern alloy steels. Peripheral speeds of 700 to 800 ft. per sec. are now frequently met with. Such speeds produce a much higher pressure rise per stage, and consequently enable the designer to reach relatively high pressures with few stages. Whereas a little over a decade ago fifteen to twenty stages were required to produce a pressure of 100 lb. per sq. in. gauge, such as is common in colliery working, a modern turbo-compressor will produce this pressure with about half of this number of stages.

The diagram, Fig. 13, shows the relation between peripheral velocity and pressure ratio obtainable in a single-stage turbo-blower when dealing with air at normal temperature and atmospheric pressure at the inlet.

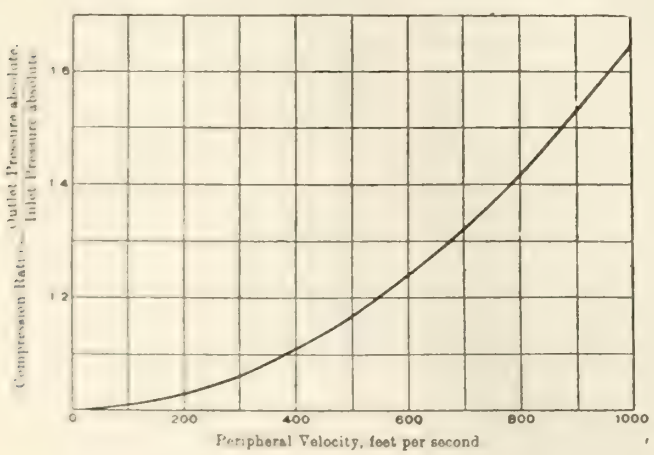


Fig. 13.

From this it will be seen that if a tip speed of 900 ft. per sec. could be used, a rise in absolute pressure of about 50 per cent. per stage could be obtained, so that in a turbo-compressor for 100 lb. gauge delivery pressure, only five to six stages would be required, provided suitable material could be obtained for the revolving discs. Doubtless the metallurgist will succeed ere long in providing the designer with a material which will comply with these conditions; in the meantime the aim is to obtain the maximum over-all efficiency with the speeds which are possible at present. To effect this, two considerations are of the utmost importance: firstly, the problem of converting the velocity energy of the air as it leaves the impeller into pressure; and, secondly, the problem of cooling the air between successive stages.

As to the first point, it will be obvious that the higher the peripheral speed of the discs, the greater will be the velocity with which the air is projected into the annular space surrounding the impeller, commonly known as the diffuser. Whilst it is possible to convert pressure into velocity by means of a well-rounded nozzle, and with an efficiency approaching unity, the converse unfortunately is more difficult. The conditions of flow are still imperfectly understood, but the following maxims must be observed if favorable results are to be obtained:—

1. The surfaces over which high-velocity air passes must be as smooth as possible.
2. The high-velocity air must be correctly guided in all directions to avoid the formation of eddies.
3. The energy conversion must take place along the shortest possible path.

In the earliest forms of turbo-compressors, the diffuser was usually bladeless; it was found, however, that the adoption of guide blades or ribs, now termed "diffuser blades," produced a higher pressure rise and also improved the efficiency. Some makers adopted cast blades integral with the casing but these were difficult to clean up; friction was excessive, and it was almost impossible to obtain the exact inlet angle for all blades as called for by the designer. To reduce the frictional effect, the spacing of the blades was rather coarse. To obtain accuracy of the inlet angle, diffusers were sometimes cast in rings separately and inserted in the stator. The latter method also allowed of polishing the guide passages, and by employing a non-ferrous alloy, closer pitching of blades and more correct form of guide passage could be obtained.

All cast forms of diffuser blades suffer, however, from the drawback of rough surfaces, which evil can only be mitigated, either by an expensive process of filing and polishing, or by providing blades of a smooth material, such as sheet brass or sheet steel, the blades being first bent to the desired shape, and then inserted in the mold and cast into a suitable ring.

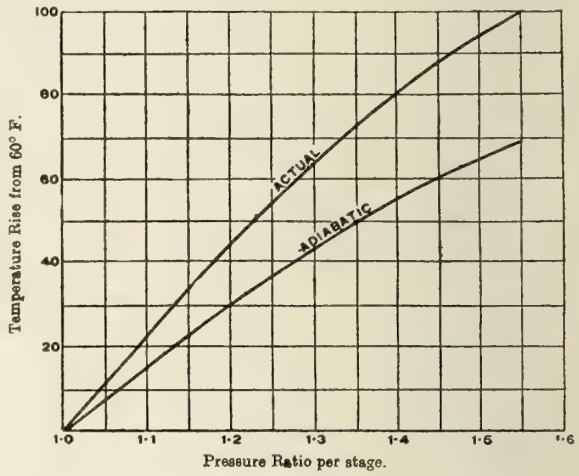

Fig. 14.

A further improvement in diffuser design has been adopted by the author's firm. The diffuser blades are made of relatively thin strips of highly polished or planished steel, or bronze, and held in place by distance-pieces which have been carefully shaped and fit into a dovetailed groove in the stator. In

this way it is possible to obtain close pitching, a very fine degree of accuracy as far as the desired inlet angle is concerned, and a means of adopting a small entrance angle, which in turn renders possible the adoption of the turbo-compressor for much smaller volumes than with the older form of diffuser. The diffuser passages are perfectly smooth, thus reducing frictional losses to a minimum; the close pitch of the blades ensures perfect guidance; the shape of the blades provides for a gradual tapering of the passage, and deflects the flow of air from a tangential into a radial direction in a very short distance. Thus the three conditions enumerated above are fulfilled in the best possible manner.

Turning now to the problem of cooling, it will be realized that the greater the pressure rise—that is, the pressure ratio—per stage, the greater will be the temperature rise. In a piston compressor the temperature at the end of the stroke will be equal to, or less than, that due to adiabatic compression; in the turbo type the maximum temperature is realized at the outlet of the diffuser blades, and generally is above the adiabatic value. This is due to the skin friction between the impeller discs and the casing walls. In consequence, the mean density of the fluid during its passage through the impeller is reduced, and this in turn adversely affects the delivery pressure as well as the energy absorbed at the compressor shaft. For these reasons it becomes imperative to employ the most thorough and efficient methods of cooling.

In the early stages of turbo-compressor construction it was possible to obtain sufficient cooling effect by water jacketing the casing. The pressure rise per stage was relatively low, the units were much smaller, and hence the amount of energy absorbed per stage, and which reappeared in the form of heat, could be abstracted with reasonable efficiency by the water-jacketed walls along which the air had to pass from stage to stage. Considering that earlier machines often had twenty or more stages to produce a pressure of 100 lb., the cooling surface obtainable in such a casing was considerable and ample.

The modern tendency of increasing the disc speed and thus effecting the total compression in a greatly reduced number of stages, clearly brings about a large temperature rise per stage. This is illustrated in the accompanying curve.

Referring to Fig. 13, and taking a peripheral speed of 800 ft. per sec., which is now possible, the obtainable pressure ratio is 1.4—that is, an increase of 40 per cent. From Fig. 14 it will be seen that the air under these conditions has a temperature rise of 80 deg. F. per stage.

In a unit designed for an output of 10,000 cub. ft. of free air per min., the energy represented by this temperature rise amounts to 350 h. p. per stage, and the equivalent heat energy must be absorbed by the cooling water if the air is to enter the next stage at the original inlet temperature. Obviously it is quite out of the question to provide sufficient cooling area for this purpose in the casing itself, and thus all makers of turbo-compressors resort to the use of intercoolers placed apart from, and usually below, the compressor casing. Considerable divergence in design is noticeable, but in principle the ultimate aim is the same—namely, to reduce the power consumption to a minimum.

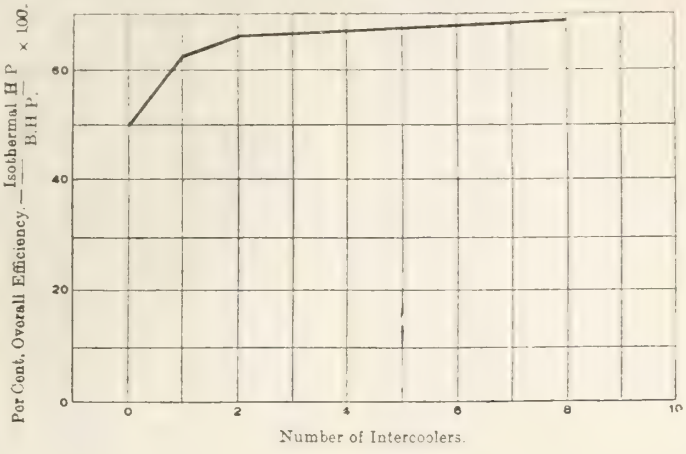

Fig. 15.

Some makers adopt a cooler after every stage; others allow the air to pass through two or three stages before it enters a cooler. The gain resulting from one or more coolers is indicated in the diagram, Fig. 15, which has been drawn for a unit of 10,000 cub. ft. of free air per minute, compressed in nine stages to a gauge pressure of 100 lb. per sq. in.

The diagram is based on the assumption that after each cooler the temperature of the air has been reduced to suction conditions. It shows that a marked gain is to be obtained by the adoption of one cooler; a further gain from two coolers, but only a slight further improvement from a cooler after each stage. This further slight gain is negatived in practice by the more tortuous path of the air, so that the best arrangement would appear to be to place a cooler after every third stage—that is, between the third and fourth, and again between the sixth and seventh. A cooler after the last stage has no effect upon the power consumption, but is adopted occasionally where cold air is desired.

The compressor casing itself need no longer be jacketed, resulting in a great simplification of this casing; further, all water joints on the casing are avoided. The intercoolers themselves are of standard design, resembling the condenser of a modern steam-turbine installation.

The tip of the blade is variously sealed against the stator by some form of packing usually leather or fibre. Where high rotational speeds are desired, this form cannot be utilised, owing to the high surface speed of slippers in their grooves. If the blade slides freely in the groove, without the use of guides and covers, its centrifugal force, and the high velocity of rubbing speed of the tip of the blade against the stator, again limit the rotational speed possible. Several methods have been used for restraining the centrifugal force of the blades to enable higher speeds to be used.

A compressor or exhauster of this type constructed by the author's firm enables high rotational speeds to be adopted by interposing between the stator and the blades a freely revolving cylinder carried on roller bearings (Fig. 12). The centrifugal force of the blades in this construction causes the freely supported cylinder to rotate, thus practically eliminating the rubbing between the tips of the blades and the stator in the old form, and, the cylinder being perforated with holes, air passes freely through the machine.

All of these types of machines, while adapted for low-pressure compressors and for exhausters, are not easily designed for high pressures, for two reasons:—

1. That the surface available for water cooling is not large compared to the volume of air passing through the machine.

2. That in all rotary machines of such general types the delivery pressure projected on the whole surface of the rotor causes a considerable total load on its bearings.

These objections have increasing force as the capacity for which the machines are designed increases.

The author hopes that the developments which have taken place in recent years in turbo-compressor design will justify the space he has devoted to this part of his subject.

He also desires to thank the various firms who have been good enough to supply him with information for the purpose of this paper.

Combustion for the Boiler Room Operator

Some Further Remarks on Draft, and Drop in Pressure Through the Brick Setting of a Boiler. Use of Draft Gauge—Combustion and the Temperature According to Theory

By T. H. FENNER

FOLLOWING on the remarks on draft in the last instalment, we will at once see that there is a necessity for some kind of gauge to show the operator the amount of intensity of the draft at any moment. Having seen that draft is measured in inches of water, which is the height of water that the difference in pressure will support, the idea of an actual water column immediately occurs. It is on this that practically every draft gauge is based, though in some cases, instead of water being used, an oil of lighter specific gravity is used. This oil lends itself more readily to showing slight fluctuations of pressure on a large scale indicator, so that a difference of .1 of an inch in draft can readily be seen by the operator.

The ordinary water column draft gauge can be very easily manufactured from an ordinary gauge glass, which can be heated and bent into the form of a U. If one end is connected to the furnace, and the other left open to the atmosphere, and the tube partially filled with water, the difference of pressure will cause an alteration of the height of the water in each leg of the U. If an ordinary wooden rule is fastened in between the two legs of the U, the difference of the water level can be read directly in inches or parts of an inch. The illustration shows this quite plainly.

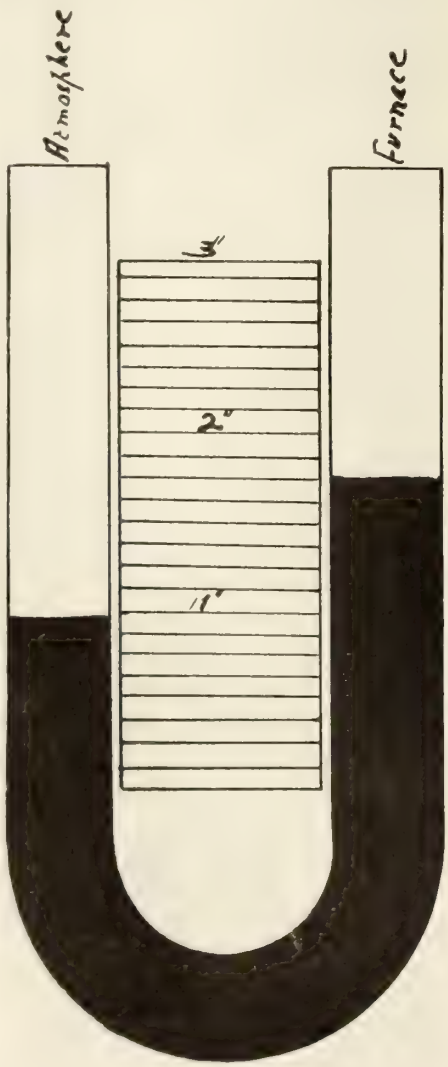
Draft gauges should always be connected in such a manner that readings can be taken from several different parts of the boiler setting, or at least three. In horizontal boilers one connection should be to the furnace, one in combustion chamber, and one in smoke box. In water tube boilers a connection to furnace, one after the first baffle, one after the second baffle, and one in last pass. Of course, this is assuming natural draft. If forced draft is used, there must be a connection to the ashpit as well, to show the amount of pressure above atmosphere existing there.

Drop Through Setting

These readings are of great assistance to the man in the boiler room, as they tell him, without the assistance of any instruments, a good deal about the condition of his brick setting. It is of great importance that the air which is used for combustion shall enter the furnace and setting only in such ways as can be properly controlled. Air infiltration through the brickwork should be rigidly excluded. Inside the setting, there should be a clear course for the gases through the path laid out for them by tubes and setting, and the friction loss should be a definite one.

For instance, suppose we have a horizontal return tube boiler, and we see by our draft gauge that the pressure over the fire is one half inch less than atmosphere, or in other words, our water gauge is showing a difference of ½ inch between the two levels. We next try the gauge at the combustion chamber, and find that difference in pressure there is .6, or 6/10ths of an inch. There has been a further drop of pressure owing to the gases having to pass over the restricted area of the bridge wall.

On trying the gauge at the breeching, we find that the difference in pressure is now .7, or 7/10ths of an inch, the loss being due to the friction of the tubes on the air in passing through.



Draught Gauge Tube.

In a water tube boiler of the horizontal type, the drop in pressure at each pass is usually about 1/10th of an inch. That is if the draft over the fire is say, .3 inches, at the first pass it will be .4 inches, at the next .4 inches, and at the last pass .5 inches. This is when conditions are normal.

Suppose now that we have in the horizontal boiler, with the same condition of fire bed, a gradual increase between the back end of the tubes and the smoke box. This will immediately denote to the attendant the presence of dirt in the tubes, which is further restricting the passage of the passes, and increasing the pressure drop. On the other hand, in the same boiler, suppose we found that between the furnace and combustion chamber we were getting no difference of pressure, what would it indicate? Generally, that the brickwork of the boiler was leaking and a sufficient volume of air was infiltrating through from the boiler room to offset the effect of the friction of the bridgewall passage. Here we have a very significant and easy pointer. When you find a greater difference of pressure between two points than is normal, look for restricted and dirty passages. When you find less difference, look for short circuiting of the gases, or infiltration of air through the setting. For instance, if in the water tube boiler, there is no drop between any two passes, it is a good indication that the baffling has fallen down, and the gases are taking a short cut from one passage to the next without going round the heating surface.

Fluctuations in the draft over the fire, with the same position of damper, warn the operator of a defect in the fire itself. For instance, if the pressure drop between ashpit and furnace suddenly increases with the damper at the same position, it is due to one or two things. First, a fresh fire has just been put on, making the fuel bed thicker, and increasing the resistance to the passage of air through it, or else the lower layer of ash, next the fire bars, is getting thicker, or perhaps has clinkered, closing off a large part of the bars. On the other hand, if the pressure difference decreases, then it is a sure sign that there are holes in the fuel bed, allowing the air to pass through too readily. Remember that air is like any other fluid or gas, in that it will always follow the path of least resistance. Therefore if there is a thin spot or a hole in the fuel bed, there will be a rush of air to that spot.

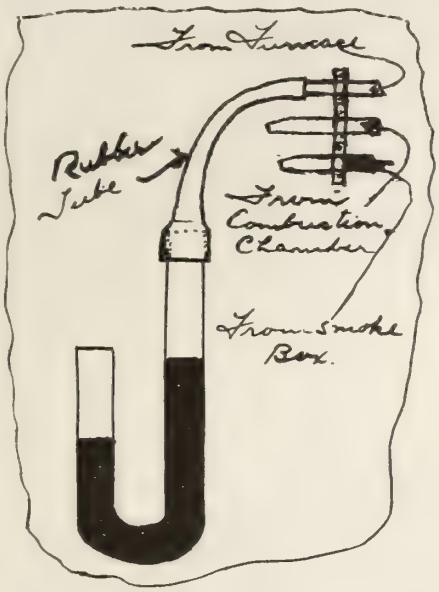
The little draft gauge then, is a pretty useful instrument, and in the small or medium size plant, where there is no other method of checking efficient combustion, it can be a great help. The first thing necessary is to instal test pipes at each of the spots where it is desired to test the draft. These pipes are all led round to the front of the boiler where the operator can see them at a glance. If he wishes to put a glass U tube on each pipe, so much the better, as then he can have every reading at a glance, but if not, he can make the rubber tube on the low pressure leg of the glass long enough to reach with ease to each pipe.

If he can purchase one of the many differential draft gauges now on the market, so much the better, as they are more reliable. The error in the home-made gauge usually comes from its position on the boiler front, where it is sometimes inclined, or the rule shifts, or the eye of the fireman or engineer is above instead of on a level with it.

Having installed the draft gauge, the next thing is to obtain some records from it which will have permanent value to the operator, or anyone that comes after him. The boiler will usually be started up with clean fires and clean tubes, (if it is a H. R. T.) on the Monday morning. Let the operator note, first with chimney damper wide open, just what the draft is at each point from furnace to breeching, with clean fires and clean tubes. Now let him close the damper down slowly, watching the surface of the fire until it becomes smoky or dull, at which point there will be practically no difference between the ashpit and pressure over the fire. The position of the damper lever or weight should be marked on the boiler wall or some convenient position when full open and when at the closed position. Now open the damper gradually until the fire looks good and bright again, and note the position and the drafts at this point. Keep the damper there, and note whether the load can be carried in that position without trouble. If so, try and carry it with the damper a little nearer the closed position. If not, open the damper slightly. Note over a period of a week the positions of the damper with different conditions of fire at which the load can be carried without undue trouble, always aiming to work with the damper closed as much as possible. Take careful notes of these results, and soon you will have very good data on the correct position of the damper for any condition of fire, tubes, and load.

The idea of keeping the damper as much closed as possible is this. In nearly every case too much air is admitted, both through the fire and over the fire, and by keeping the damper at the least possible opening for good work, this loss is cut down, and there is a certain amount of leeway left for damper adjustment as the fire thickens. With too many men, the damper is worked at its full open position irrespective of the thickness of fuel bed.

Some one of the numerous automatic damper regulators on the market are preferable to hand adjustment. Those systems which give a balanced draft, that is, that tend to keep the pressure



Flexible Draught Gauge Connection to Furnace Combustion Chamber and Smoke Box.

in the furnace the same as that of the outside air have the advantage of offering the least facility to air infiltration. These, of course, are applied to boilers working under forced draft, as under natural draft, the pressure over the fire must always be less than atmospheric.

The Process of Combustion

If we leave a piece of iron or steel to the weather, for any length of time, the oxygen of the air gradually combines with the carbon in the steel, the result being the formation of oxide of iron, which gradually flakes off and disintegrates, in the form we know of as rust. If the process is left long enough, the whole mass will disappear, having been resolved into its component parts. This process is attended with the evolution of heat, but the process is so gradual, that the heat is not apparent to the senses. It is a process of slow combustion. We have seen that it requires a definite amount of air, to burn one pound of coal or oil, or wood, and in order that this combustion may proceed rapidly, the oxygen must be mixed very thoroughly with the carbon and volatile gases of the fuel. The resulting heat is given off so quickly, that the temperature rises, and if the gases are confined in a comparatively small space, and are in direct contact with conducting surfaces, the heat will be transferred through these conducting surfaces to whatever there is on the other side. In the case of the boiler the conducting surfaces are the tubes or shell of the boiler, and the water is on the opposite side of the conducting material.

We can, with the help of the chemist, see what temperature we may expect to derive from the burning of one pound of fuel with the exact proportion of air, and after that we shall be in a position to appreciate the effects of getting a surplus quantity of air in our furnace. The temperature given by the following formula, is of course theoretical, and is never reached in practice, but it does form a guide as to possibilities. The formula is from Kent's Handbook, and is made on the assumption that the specific heat of the gases in the furnace is .237, and that the hydrogen and water content of the fuel exist in the combustion chamber as steam.

Let C equal percentage of carbon.
Let H equal the percentage of hydrogen.
Let O equal the percentage of oxygen.
Let W equal the percentage of moisture.
Let f equal lbs. of dry air per lb. of fuel.

$$\text{Then } \frac{616C + 2220H - 3270 - 44W}{f + 0.02W + 0.18H} = T$$

Suppose we had a fuel of the following composition: Carbon 78 per cent., hydrogen 5 per cent., oxygen 3 per cent., moisture 6 per cent. The weight of dry gases per lb. of fuel would be, under theoretical conditions, approximately 11.5 lbs. Applying these figures to the formula

$$T = \frac{616 \times 78 - 2220 \times 5 - 327 \times 3 - 44 \times 6}{11.5 - .02 \times 6 - .18 \times 5}$$

which come to 4831. This represents the rise of temperature of the furnace gases, if there were no losses.

In practice the temperature of the furnace ranges from 1400 deg. to 2500 deg., which is a long way from the theoretical. It will be seen that the pounds of flue gas per lb. of coal is a division in the formula, so that every increase in the air admitted per pound of fuel tends to reduce the temperature.

We can make an approximate estimate of the temperature of combustion without any elaborate formula. Suppose we have fuel of a heat value of 12,000 B. t. u. per pound. If we burn it with the minimum amount of air, say 12 lbs per lb. of fuel, we have 12,000 units available to raise the temperature of 12 lbs. air. The specific heat of air is .24 so that each B. t. u. will raise roughly 4 lbs. air 1 degree. That is, 12,000 B. t. u. will raise 48,000 lbs. air 1 degree, or will raise 1 lb. 48,000 degrees It will then raise 12 lbs.

$$\frac{48000}{12} = 4000 \text{ deg.}$$

if there are no losses.

Now, if we use, instead of 12 lbs. air, 24 lbs., which is 100 per cent. excess we bring our temperature down to $\frac{48000}{24} =$

2,000 deg. Here we see at once the effect of excess air.

Composition of Flue Gases

We can now consider the composition of the products of combustion, or flue gases, and the effect of different combinations, and what can be learned from an analysis of the gases.

The process of combustion is a chemical one, as we have seen, but in order to get a sufficiently rapid combustion, we have to aid it with some mechanical effort. That is, in starting a fire, we in the first place, supply heat by means of friction to some chemical, which is in contact with the air, this heat being sufficient to cause ignition, after which the air supports the combustion until the material is entirely changed. This somewhat lengthy explanation may be reduced to the fact that we strike a match. We then apply the flame of our match to some material such as paper, excelsior, or waste soaked in oil, which has the property of rapid combustion owing to both its composition, and the fact that it is loose in structure, and affords ample opportunity for the mixture of air. This in turn ignites with a rapid rise of temperature, and this temperature is sufficient to liberate the volatile matter in a small quantity of coal in contact with the flame. This volatile matter, on coming into contact with the air and the flame from the paper, combines with the oxygen, developing heat, and igniting in occasional puffs of flame. At this stage, however, there is more smoke than flame, showing that the temperature is not yet high enough for rapid combustion, and that the volatile matter is escaping without being consumed, and is carrying heat with it. Gradually however the temperature increases, and the gases ignite, while the solid carbon also begins to glow, and more coal can be added, until the fire is thoroughly built up and the temperature has reached the point of finality. It is at this stage that we can make our real study of the combustion, and determine whether the results we are getting are good or bad.

(To be continued)

TORONTO TECHNICAL EVENING CLASSES

The evening classes in connection with the Toronto Technical Schools open for the 1922-23 session on October 2nd. The classes for engineers will be carried on as usual, there being two classes, one for first year students, and one for second year. The first year classes are designed for those who wish to obtain elementary knowledge in connection with steam engineering, and especially for those who are intending sitting for the third class examinations of the Ontario Board of Examiners. These classes will be held at the Central Technical School, Harbord Street, on Monday and Thursday evenings, commencing at 7.45 p. m., and will be under the direction of Mr. M. B. Watson, Director of Engineering, Toronto Technical Schools.

The classes for the second year students, which are of a more advanced nature, and intended for those who wish to obtain the second class certificate of the Ontario Board of Examiners, will be held on Tuesday and Friday evenings, the teacher being Mr. T. H. Fenner, editor of "Power House." The classes will commence at 7.45 p.m. each evening.

Students in these classes are expected to pay a fee on entering, which will be returned to them at the end of the season if they have attended 85 per cent. of the classes. Full information as to registration, etc., can be obtained from the Registrar's office, Central Technical School, Harbord Street.

Don't forget classes start October 2nd.

PREPARING FOR CONVENTION

On Monday evening, September 11th, a meeting was held at the residence of Mr. C. B. Turner, 894 Bathurst Street, Toronto, of the joint committee of the Supplymen's Association, and the C. A. S. E. The object of the meeting was to complete preliminary arrangements for the 1923 convention, which is to be held in Toronto on June 25 to 28, 1923. There were present C. B. Turner, Gordon Keith, of "Canadian Manufacturer," H. H. Gee of the Jenkins Valve Co., L. M. Archibald, of the Dart Union Co., H. Fletcher of the Garlock Packing Co., representing the Supplymen's Association; and Mr. G. A. Brown, secretary Toronto branch, J. Quinlan, R. McLaren, and G. J. Soucy, representing the C.A.S.E.

The questions discussed were those of sites and buildings suitable for holding the convention, and ways and means of ensuring its success. Committees were appointed to deal with these features, and report to the next joint conference which will be held on October 10th next.

C. A. S. E. EDUCATIONAL WORK

First List of Questions on Fuels, Coal, Wood and Refuse

(1) What is the heat-value of the different kinds of coal as mined?

(2) What are the causes of loss of heat value between the mine and the time of its actual burning?

(3) What is the average heat value of fuel-oil and what relation has specific gravity to variations in heating value?

(4) How would you compare the heat value of a ton of bituminous coal (13,500 B. t. u.) at $8.50 per ton with a barrel of fuel-oil (18,000 B. t. u.) at 10c. per gal. (Imp.)

(5) What is the average heat of a pound of soft and of hard wood?

(6) Compare coal of 12,500 B. t. u. at $7.50 per ton with a cord of hard wood at $9.00 per cord and show which has the best heat value.

(7) What is the average moisture content of the different kinds of refuse burned in saw-mills and tanneries?

(8) What effect has the high moisture content with regard to its heating value?

(9) What are the two principal causes of fuel loss common to all kinds of fuel and all types of boiler?

(10) What other causes are there of fuel losses—(a) as regards the furnace (b) as regards the boiler?

General Educational Committee of the C. A. S. E.: Geo. J. Soucy, chairman and acting secretary; T. H. Fenner, (Editor of Power House) publicity; E. C. Hanson, (Power-Engineer) Questions.

Any engineers who wish to take advantage of the educational work of the association, who are in a district where there is no branch, should communicate with the grand secretary, Mr. L. J. Ellis, Hamilton.

TORONTO BRANCH C. A. S. E.

"Power House" is in receipt of the following letter from the Toronto No. 1 Branch of the C. A. S. E. through the secretary, Mr. Geo. A. Brown:—

I am instructed by Toronto No. 1 C. A. S. E. to thank you for the donations of two subscriptions to the Power House, and the two steel rules in leather cases, as prizes for our recent Grand Annual Picnic, as an appreciation of your very kind interest in our purposes.

(Signed) GEO. A. BROWN,
Secretary.

A COMPACT PORTABLE PUMP

There was recently despatched to the Far East a portable pumping set specially designed to work in very constricted spaces. This pump carries a seven horse-power paraffin engine; but it is so designed and mounted that it can be readily accommodated in a space 4 ft. long and 5 ft. high. The pump is capable of delivering 250 gallons per minute against a height of 30 ft. Water-cooling is provided, and in the event of the water available being dirty or otherwise unsuitable for cooling purposes, a radiator or fan can be brought into operation. With a view to easy transport the pump and engine are mounted on a frame with wheels, and the whole arrangement can be easily hoisted in a crane.

VALVELESS GEARLESS ENGINE

The idea of an engine without valves or gear has been realized in Great Britain by th econstruction of an engine which in the works at least, has been given remarkably promising results. This engine has three cylinders; and except for the ports it has no valves. There is not a single gear wheel and all the usual cams, shafts, tappets and springs and even the timing gear are cut out.

Flywheel Explosions and Their Prevention

Simple and Reliable Rules for the Computation of Stresses—General Considerations Influencing Types of Wheels—Remedies Suggested for Dangerous Conditions Include Preventive Measures in Connection With Governors and Governor Drives

By E. B. TOLSTEAD

STATEMENTS have been made frequently that exploding flywheels cause more damage than exploding boilers; whether or not this statement is true, it is true that state and city regulations practically disregard fly wheels but we have boiler regulations wherever we turn. It must be only a question of time when regulations and laws will protect the lives and property against flywheel accidents, as they now protect them against other hazards.

The limiting the speeds for flywheels and pulleys of the best design have been determined theoretically and by tests, and the figures agree very well. We know that a given wheel cannot speed beyond a certain point without giving way, and the speed depends among other things upon the type of wheel.

Users of fly wheels have bought their engines and other machinery equipped with flywheels, and they have assumed that the flywheels were safe for the speeds secified. Some purchasers have gone further than this. They have treated their flywheels and pulleys as they would their automobiles and they have run them at as high speeds as conditions outside of safety would permit. They have learned that faster working machines, in many cases, increase output and they have speeded up without giving the flywheel a thought.

Nearly all factory men have heard that the belt has a limit of speed beyond which there is disadvantage in going. This has been the salvation of the pulley for it has held down the rim speeds of pulleys. It should be remembered, however, that a split cast iron pulley, or flywheel with a flanged joint carrying a belt which runs at 5,000 feet per minute is going altogether too fast. A solid cast iron pulley can run at about 6,100 feet per minute and still have a factor of safety of 10 which is the figure that should be used in pulley and flywheel work.

Unfortunately, the correct speed for the belt does not always hold down flywheel speeds. For example one might have an engine directly connected to a line shaft having pulleys, let us say 4 feet in diameter. This engine might have a flywheel 10 feet in diameter. The flywheel speed could then be in the neighborhood of 12,000 ft. per minute without overspeeding the belts.

Computation of Stresses

There are three types of wheels in common use: the flywheel with a single piece rim, the flywheel with a split rim and with a link joint, and the flywheel with a split rim and with a flange joint. The solid wheel can be used only if the diameter is less than 10 feet on account of the dificulties in construction and shipment. The link jointed wheel can be conveniently adopted only where the rim is thick and since such a rim is not frequently used for belt or rope driving, where such a drive is necessary a solid wheel or flange jointed wheel is used.

One can usually get an idea of the safety of his flywheel equipment from the rim speeds, but since the computation of the rim speed requires the multiplication of three figures, namely, the revolutions per minute, the diameter of the wheel, and the constant pi, it has been found more convenient to omit the constant pi and to think of flywheels in terms of the revolutions per minute and the diameter.

The following tabulation shows the products of the revolutions per minute and the diameter which should not be exceeded if it is desired to keep the factors of safety at 10 or above:

(a) For solid cast iron flywheels the product of the revolutions per minute and the diameter (in feet) should not exceed 1,937.

(b) For link-jointed cast iron flywheels the product of the revolutions per minute and the diameter (in feet) should not exceed 1,500.

(c) For flange-jointed cast iron flywheels the product of the revolutions per minute and the diameter (in feet) should not exceed 968.

If, in any case, it is found that the product referred to above exceeds the figures suggested for the type of wheel which is operating, a further investigation of the conditions should be made.

The diameter referred to above is not taken as the outstide diameter of the wheel but as the mean diameter of the rim.

From Marks, Kent, and similar handbooks, we may obtain formulae for centrifugal force which can be finally worked into the following:

Stress in a cast iron rim, due to centrifugal force, equals $.0002664\ (RD)^2$.

If we take the accepted figure of 10,000 lbs. per square inch as the maximum tensile stress which a cast iron rim is capable of withstanding, and use a factor of safety of 10, which means an allowable stress of 1,000 lbs. per square inch, we have:—

1,000 equals $.0002664\ (RD)^2$ or RD equals 1937.

A joint in a flywheel is like a riveted joint in a boiler, in that one cannot exceed a certain efficiency. For a flange-jointed wheel this maximum efficiency is 25%. Therefore, while we can allow a stress of 1,000 lbs. per square inch in a rim of the solid wheel, we should limit ourselves to 250 lbs. per square inch in the rim of the flange-jointed wheel. Then in this case:—

250 equals $.0002664\ (RD)^2$ or RD equals 968.

Because the efficiency of a link-joint does not exceed 60%:—

600 equals $.0002664\ (RD)^2$ or RD equals 1,500.

Now, having the speeds of several wheels at which we will have factors of safety of 10, the next question to be determined is the probable bursting speeds. Since the stress increases with the square of the speed, it follows that the wheels can operate not ten times as fast but 10 times as fast as is indicated by the figures above, before they will actually burst. The 10 is approximately 3.16, therefore, the highest speeds at which wheels are likely to be able to attain are:—

(a) Solid Wheels	6,120
(b) Link-jointed wheels	4,740
(c) Flange-jointed wheels	3,059

In order that you may know the approximate factors of safety of your wheels, the following formulae may be applied:—

For a solid wheel the factor of safety equals —

$$\frac{(1937)^2 \times 10}{(RD)^2}$$

For a link-jointed wheel the factor of safety equals—

$$\frac{(1500)^2 \times 10}{(RD)^2}$$

For a flange-jointed wheel the factor of safety equals—

$$\frac{(968)^2 \times 10}{(RD)^2}$$

As explained above, the figures given are those for wheels with the best possible design of joint.

Therefore, if you make a computation from any of the formulae used above you may be sure that your wheel is not better than the result obtained from an application of the formulae but that it is less good if the design is not of the best.

The engineer who is called upon to investigate a fly wheel, finds it necessary to measure the wheel very carefully and

* Read before the National Safety Council, Detroit.

to make practically a duplicate of the original fly wheel drawing. From this he determines the stresses in the various parts of the wheel. Link-jointed wheels and flange-jointed wheels furnish complicated mathematical problems for him. A few assumptions are necessary. Most of these happen to fall on the side which would indicate the fly wheel to be safer than it is, so that when the engineer has made his computation he can only say to you "I know that the stresses are this high and I do not know how much higher they may be. Similarly I know that the factor of safety is not above this figure."

One assumption which is frequently taken exception to but which, nevertheless, is justified, seems to fall on the side of indicating the wheel less safe than it actually is. This assumption is to the effect that the fly wheel is a ring revolving in space. In other words, it assumes that the spokes do not tend to hold the wheel together. While there are undoubtedly wheels which are partially held in place by the spokes, there have been enough cases proven of actual compression against the spokes to justify those who calculate wheels in considering that the spokes at least, do not help to hold the rim together.

If the engineer could watch the erection of the flywheel and could make a record of the conditions existing as the flywheel goes into place, much that he later questioned could be answered. I have in mind a corporation in Chicago which erected a power house and put in a number of reciprocating engines. Link-jointed flywheels were used since the engines were direct connected to generators and since belts and ropes were unnecessary. When the last link was cooling down, after it had been shrunk in place, it broke. This made the company which had bought the wheel suspicious and they drilled a small hole in each of the other links. Although the link was several inches wide and the hole was probably only ¼ in. in diameter, the removal of this small amount of material was of sufficient importance so that several other of the links broke. The reason for the breakage was that the links had been made too short in the first place. Consequently, it had been necessary to heat them very hot and as they cooled to the room temperature the stress put in them was too great. It exceeded the strength of the link in only one case but had the other wheels been run up to speed it is quite possible that all of them would have broken. Had the erecting engineer carefully measured the link itself and the place where it was to be fitted, he would have been able to have determined the stress that would have been put in the link after it had cooled, or had the company's engineer noted the high temperature to which the links had been heated, he would have known that there was something wrong in the de-

Any company which has important wheels to set up should assure itself that matters of this kind are not overlooked, since it is practically impossible to determine conditions after erection without tearing the wheel down.

Causes of Flywheel Accidents

While the principal cause of fly wheel accidents comes from overspeeding, which may be normal or momentary, there are many contributing causes and several independent ones. The principal divisions are overspeeding, overloading, and failures due mainly to defects, flaws, and improper handling. The causes of overspeeding may be divided and subdivided as follows:

(a) Normally high speed not necessarily exceeded when wheel breaks. (Failure due to this cause is frequently in combination with "a" "b" or "c" under next heading.

(b) Breaking of engine parts.

(c) Breaking of engine belt.

(d) Engine belt running off flywheel.

(e) Breaking of governor belt.

(f) Slipping of governor belt.

(g) Governor belt running off pulley.

(h) Derangement of governor, which may be subdivided as follows:

1. Struck by flying parts.
2. Failure of governor pulley.
3. Loose or lost set screw.
4. Loose or lost key.
5. Gear or gears broken.
6. Fly ball off.
7. Parts broken or sheared off.
8. Insufficient lubrication.

(i) Derangement of governor valve gear.

(j) Loss of load (frequently when an engine speeds slightly, the first act on the part of men operating machines is to throw off these machines. This increases the likelihood of the engine speeding.)

(k) Circuit breaker blown out, burning out of armature, or electrical load otherwise dropped.

(l) Improper adjustment of engine stop, governor, or valve gear, or governor or valve gear parts blocked or otherwise made inoperative, or engine stop out of commission.

Overloading may be divided as follows:

(a) Clogging of machinery in mill.

(b) Unusual number of machines forced at same time.

(c) Careless or ignorant handling of friction clutches.

(d) Short circuit of driven electrical machinery.

(e) Sudden stoppage of engine.

Some of the miscellaneous causes of flywheel accidents may be divided as follows:

(a) Failure of wheel due to flaw.

(b) Failure of wheel due to improper material. (For instance, too high a percentage of phosphorous in a wheel is likely to make it brittle. Jobbing foundries frequently use phosphorous for small molds, which must flow readily. The effect of phosphorous in iron is to make it flow at a lower temperature than if the phosphorous were not present.)

(c) Failure of wheel due to crystallization.

(d) Failure of wheel due to internal stresses.

(e) Failure due to accidents to engine.

(f) Failure of wheel due to improper design.

(g) Failure due to dirt or foreign materials carried in rim.

(h) Failure due to holes drilled in rim.

(i) Failure due to increasing diameter by adding on to rim.

(j) Tight keys.

(k) Wheel struck by flying objects.

(l) Belt pull.

(m) Loose bearings.

Of the above causes derangement of the governor is probably the principal one, and broken belts the next most important one.

Remedies for Dangerous Conditions

Generally speaking, remedies which can be applied for the prevention of fly wheel accidents, may be found among the following:

(a) Better governors.

1. Triple rope drive instead of single belt drive for governor.
2. Governor sheaves to be keyed, and the unused portions of keyways to be filled in.
3. Governor sheaves to have suitable guards of substantial construction.
4. Safety cams on all Corliss valve gears.
5. Guards around governors.
6. Governor gearing enclosed in oil-tight covers, readily detachable for inspection.
7. Couplings, set screws, keys, bolts, etc. in moving parts countersunk.
8. Better care of governors.

(b) Better care of engine parts, belts, etc.

(c) Lower flywheel speed.

1. Two small wheels instead of one large one.

(d) Solid wheels instead of jointed wheels, or link jointed wheels instead of flange jointed ones.

(e) Steel, wood, or other wheels adapted to high speeds instead of cast iron wheels.

(f) Better design of equipment.

1. Avoidance of overload.
2. Arrangement of steam piping to avoid breakage.
3. Avoidance of materials fastened on outside of pulleys or flywheels, and avoid holes drilled in such pulleys or flywheels.
4. Locate engines and equipment so that the least possible damage will be done in case of breakage.
5. Space in flywheel pits for broken belts.
6. Signals from engine room to machine room, and vice versa.
7. Engine stops.
8. Automatic valves on boilers.
9. Bracing of dangerous wheels with tie rods.
10. Frequent operation and testing.

The Better Types of Wheels

The table shown, which is made up for 10 ft. cast iron wheels, shows the relative

balancing effect of wheels at various speeds and the factors of safety of two types of wheels, the increase of speed necessary to break the wheel, and relative elapsed times necessary to reach breaking speed. It should be understood that the balancing effect and the times necessary to reach breaking speed are relative figures only.

Ten Foot Diameter Cast Iron Wheels

		Flange Jointed Wheel			Solid Wheel		
Revolutions per Minute	Balance Effect	Factor of Safety	Increase of speed Necessary to break	Time to reach Breaking Speed	Factor of Safety	Increase of Speed Necessary to break	Time reach Breaking speed
96.87	1	10.00	2.16	1	40.00	5.32	4.33
150.00	2.41	4.16	1.04	0.84	16.62	3.08	4.18
193.74	4.00	2.50	0.58	0.67	10.00	2.16	4.00
306.00	10.01	1.00	0.00	0.00	4.00	1.00	3.33
612.00	40.00	....	....	....	1.00	0.00	0.00

Referring to the table above, the advantage of the solid wheel over the flange jointed wheel is readily understood. Take, for instance, the third line table. This assumes a 10 ft. wheel to be operated at approximately 194 revolutions per minute. The balancing effect of two wheels is naturally the same. The factor of safety of the solid wheel is four times as great as that of the flange jointed wheel. It must be increased in speed another 216% before it breaks, whereas the flange jointed wheel need be increased only 58%. While this increase is going on the engineer has six times the time to get the engine stopped that he would have with the flange jointed wheel. If, for instance, the time with the flange jointed wheel should be 10 seconds he would have a full minute to stop an engine carrying a solid wheel. Few engineers could be expected to get the steam shut off their engine in 10 seconds. Most of them could do it in a minute if they had the nerve to make the attempt.

Solid case steel wheels or built-up steel wheels are capable of running at higher speeds than cast iron wheels. Wooden wheels also may run faster than cast iron wheels, providing they are properly made. A well made wooden wheel may be run about 54% faster than the best cast iron solid wheel and a well made built-up steel wheel may be run about 88% faster than a solid cast iron wheel. Usually however, cast iron wheels, because of their lower cost, are adopted.

It is unfortunate that the subject of the hazards of fly wheels cannot be completely covered in a paper of this length. For instance it is regrettable that there has not been space to discuss the requirements which an engine stop should meet. The engine stop should be considered to be one of the best protections against the fly wheel hazard, but every care should be taken in choosing the engine stop. If, for instance, an engineer is slowing down his engine with a fair chance of getting the steam shut off before the fly wheel bursts and the engine stop takes hold of the throttle, winds his arm into it and becomes blocked with the throttle half open, then neither the stop nor the engineer can afford a fly wheel explosion. This has actually occurred.

BOOK REVIEW

The C. A. Dunham Co. have issued a booklet entitled the "Dunham Hand Book" featuring their line of heating appliances, together with some useful tables, and a glossary of heating terms. As the introduction states, "it is not to be considered as a text book, but as a hand book, a ready reference for those specifying, installing, or using the Dunham Products."

The B. F. Sturtevant Co. of Hyde Park, Boston, Mass., has just issued a new 72 page Engineering Bulletin on pneumatic collecting and conveying.

It contains 33 pages of pictures and diagrams, 17 pages of useful tables—how to find the size of fans, the suction, volume, R.P.M. and horsepower for any system, cubic feet of air handled per minute, size of pipe and ducts used, and various other valuable tables.

Data is also given on dust collecting from grinding and polishing machines, tumbling barrels, sand blast machines, coal breakers, shoe machinery and the removal of fumes, gases, etc. In addition, there are parts on the conveying of pulverized coal, fibrous materials, coffee, ashes, wool, wood chips, etc., etc. It is a most comprehensive treatise on pneumatic collecting and conveying systems.

A copy will be sent on request.

The McGraw Hill Book Company, 370 Seventh Avenue, New York, have just issued "Steam Engine Principles and Practice," edited by Terrell Croft. The contributors to the work are Messrs. H. C. Croft, A. J. Dixon, E. R. Powell and Edmund Sirosky, of the Terrell Croft Engineering Co. The book is divided into divisions, and these again are subdivided into sections, which makes reference to any particular point very easy. There are in all sixteen divisions, and over five hundred sections. The book covers everything that can be known about a steam engine from the operator's point of view, and embraces all the different types, their operation, their testing, and selection. The book is profusely illustrated. There are problems set at the end of each division, and the solutions of these problems are given at the end of the book for the student to correct himself. The price in the States is $3.50.

B. & S. THICKNESS GAUGE

The Brown and Sharpe Thickness Gauge No. 646, affords a relatively inexpensive precision tool of this type, which it is claimed, fills an important need. It contains six blades: .0015 in., .002 in., .003 in., .004 in., .006 in. and .015 in. in thickness, which can be used together or singly and give a variety of measurements up to .0315 in. These sizes have been selected by the makers as ones most frequently used, and to give a complete range of measurement. These blades are not rolled to size, but

New Thickness Gauge

are ground to the correct thickness. The gauge has been designed with an eyelet in one end so that it can be carried on a ring or hung up. It is especially useful to the motor mechanic and to automobile drivers, for it answers the requirements in many places around a car: for setting valve tappets, distributor headpoints, spark plug gaps, fitting pistons and determining the size of shims for joints or parts where there is play or looseness. The manufacturers state there is a broad range of use for this gauge.

This new tool is described in detail, in a pamphlet issued by the manufacturers.

CATALOGUE

The Canadian Ingersoll-Rand Co., of Sherbrooke, Que., have just issued a new catalogue covering their complete lines of engineering equipment. The book is prepared in a very convenient and interesting style, being subdivided into fifteen sections, fourteen of which are devoted to some particular class of product and the last portion to a general collection of tables, formulae, etc., for the service and reference of engineers. The catalogue is compiled in loose-leaf card index form, permitting the removal or addition of certain pages or sections when necessary. The book contains 230 pages held together in an expansion cover by means of brass screws. Three hundred halftone cuts are used to illustrate the various lines.

BOOKLETS

A booklet, known as circular 1579-B, containing general information and technical data for cutting micarta gears and pinions, has recently been issued by the Westinghouse Co. for distribution among gear cutters. The book contains a great amount of useful information for gear manufacturers.

The Season Opens

FOR EVERY kind of sport there is an open and a closed season, and to those who look on the improvement of the mind, and a better knowledge of their profession, as a pleasure, there is an open season for study. During the long bright days of summer, a man's recreation time is better spent out in the open, at whatever relaxation he particularly affects, than in the poring over books. Of course, if there is a special reason to perform a certain task or pass some examination then study is the order, to the exclusion of anything else. In general, we think it is better for a man to build up his bodily health, and incidentally make his mind all the keener, while the fine weather lasts, and reserve his studies for the long winter nights, when time may hang heavy without some hobby. This open season for study may be said to last from October to April, and to those who wish to avail themselves of it there is ample opportunity. In every centre of population there is now a technical school, at which classes in practically every subject for which there is a demand are held. The fees for these classes are nominal, and in most cases are returned if a certain number of attendances are put in during the season. For the stationary engineer who wishes to gain some better knowledge of the principles of his work, these classes offer a fine opportunity. They should be well attended wherever they are held. The better the attendance, the more money will the department feel justified in spending on that particular class, and the better will be the results all round. If a man cannot attend a technical school, there are other means open to him. The Canadian Association of Stationary Engineers are making a special effort this year with their educational work, and any man who attends their meetings at any convenient branch cannot fail to derive benefit from it.

To-day is the day of the educated man, in whatever line of endeavor he makes his living. Knowledge is power, and no opportunity to acquire it should be lost. At the worst, a man can study at his own home by reading, but generally speaking, the average man can make far better progress when he has the assistance of others to compare notes, or to straighten out difficult propositions.

To every ambitious engineer, young or old, we would say, choose your method and line of study for the coming winter, and get into it with the earnest intention of sticking to it, just as soon as the last day of September has marked the passing of summer.

Central Heating Plants

ALTHOUGH the coal strikes in both the anthracite and bituminous fields are over, and coal is being produced, there still remains the menace of a tie-up in transportation facilities. Time alone will enlighten us on the real situation as regards coal for this winter.

These periodical coal shortages never seem to have any effect on the public mind, once they are over. While the inconvenience and in some cases actual hardship is present, there is much loud talk, but once the pinch is over, it is promptly forgotten.

Every one of these situations is an argument against the individual domestic heating plant and in favor of central stations There is but little question that the coal used in heating one hundred homes in the individual manner, would heat double that number if burned in a central heating plant. Apart from that economy, the central heating plant can burn any low grade coal, and does not have to be supplied with anthracite at fancy prices. It can afford to carry very much larger reserves. If one hundred homes have at the beginning of winter one thousand tons of coal in their bins, it is about the limit. One thousand tons in reserve in the central station plant would be the necessary amount to heat two hundred homes for the winter. Owing to using a much lower grade of coal, for the same amount as the householders put into their one thousand tons, the central station could secure approximately two thousand tons. So it goes, in every department. The time is coming in large centres of population, when there will be no other means of heating than the central station. It may not be in the very near future, but we are convinced that it is an absolutely assured development of our modern civilization.

Fly Wheel Precautions

EVERY reader should read with interest and attention the article in this issue, on the prevention of fly wheel explosions. Any one who has ever witnessed the bursting of a heavy flywheel, or who has been on the scene of the accident before the debris has been cleared away, carries for ever in his memory a picture of the scene. If the accident has been attended, as this kind of accident frequently is, with loss of life, or injury to limb, the picture is more deeply impressed. Those who have not actually witnessed these scenes, must have read of them on many occasions as they were reported in their technical magazines, and in the daily newspapers.

Every one who has charge of an engine which has a flywheel, should realize the enormous potential force stored up in that wheel. With normal running, this force is exerted in a beneficial manner, and serves to make things run smoothly. That same force liberated in a moment, and applied to carrying enormous masses of metal through the air at high velocity, smashing everything in their path like a high explosive shell, is a very terrible thing. The writer of this article has gone very carefully into the question of flywheel stresses, and the prevention of accident, and a careful perusal of his statements will be time well spent.

Progress in New Equipment

NEW LATERAL RETORT JONES STOKER

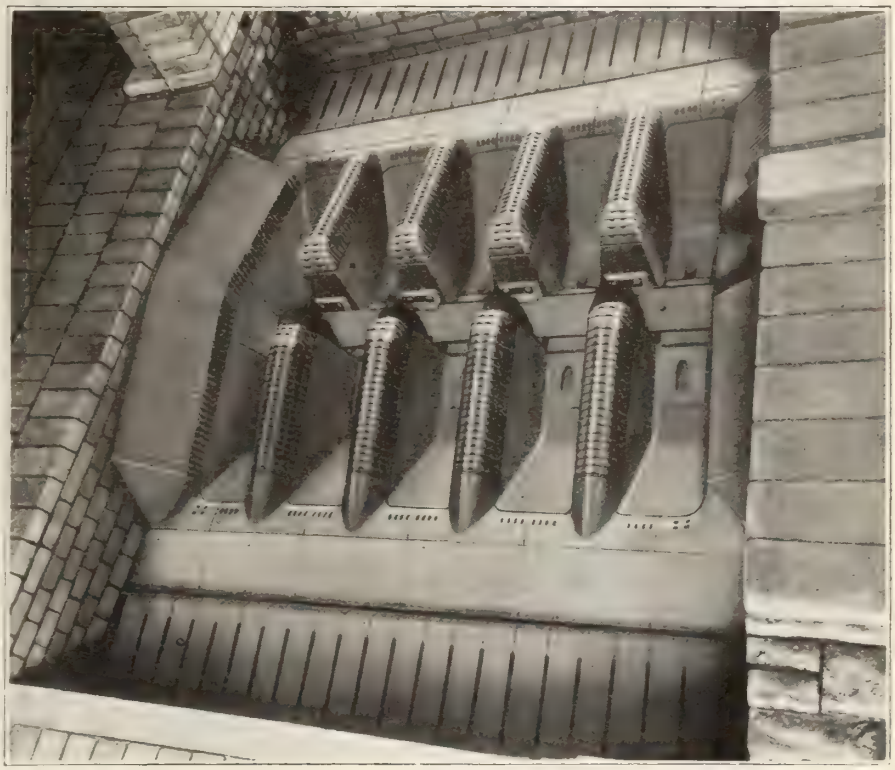
The latest product of the Under-Feed Stoker Company of Canada, Limited, is the lateral retort underfeed stoker.

The distinctive and exclusive feature of this new stoker is the fact of its being an all under-feed side cleaning equipment. The coal is fed from underneath the entire fuel bed and not, as in other side cleaning types, by a combination of under-feed and over-feed methods. This all under-feed firing provides the maximum of temperature over the whole width and depth of the grate surface.

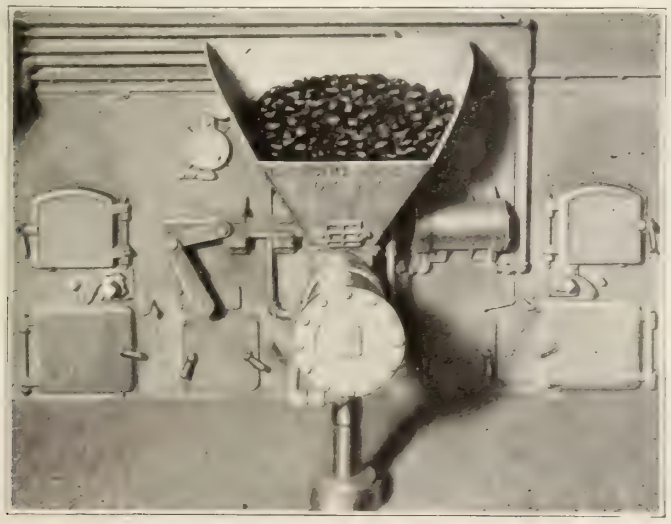
A glance at Fig. 1 illustrates clearly why this is so—note the air openings distributed over the whole surface—note the depth of retorts, which means large coal reserve.

The lateral retort stoker consists of a main retort extending from the furnace front to the bridge wall. From this main retort, at right angles, on each side, lead off four or five lateral retorts (depending on capacity of stoker).

The coal is fed in from hopper on the boiler front, see Fig. 2, by steam actuated ram, through the front wall opening on the right, Fig. 1, and is distributed front to rear by a pusher plate. Reciprocating shoes, seen in the bottom of the laterals Fig. 1, take the coal from the main retort and distribute it upwards and outwards to the dump plates at the sides. These shoes are actuated through heavy link connection by the small piston and cylinder on the right of the hopper, Fig. 2. This is independent from main cylinder, so that timing of the strokes of these shoes may be controlled independent of the main ram.



As will be seen in Fig. 1, the lateral retort stoker is of the side-cleaning type; in this respect it differs from the Jones A-C Stoker, which cleans to the rear, otherwise it is simply two Jones A-C Stokers set back to back and fed from the main retort.



The dump plates are counterbalanced and have interlocking tips on outer ends. An auxiliary supply of air may be admitted under the dump plates to provide for the burning of any particles of coal which reach them.

The lateral retort stoker is so designed as to obviate the necessity of large ash pits or basements underneath—and as it is set very low it may be installed under low-set boilers already in service without great difficulty.

If the furnace is too narrow to take the full size stoker, the half lateral may be used. This is comprised of the main retort and laterals on one side only, the main retort being set at one side of the furnace and the laterals leading off from it to the dump plate at the other side—one ash pit only being necessary.

The automatic adjustment of fuel and air is the same as with the Jones Standard and Jones A-C Stokers. The Cole automatic valves, which control the movements of the stoker pistons, are belted to the fan shaft, the fan engine being controlled by an automatic regulator which operates on variation of fuel and air is speeded up or slowed down in accordance with the steam requirements of the plant.

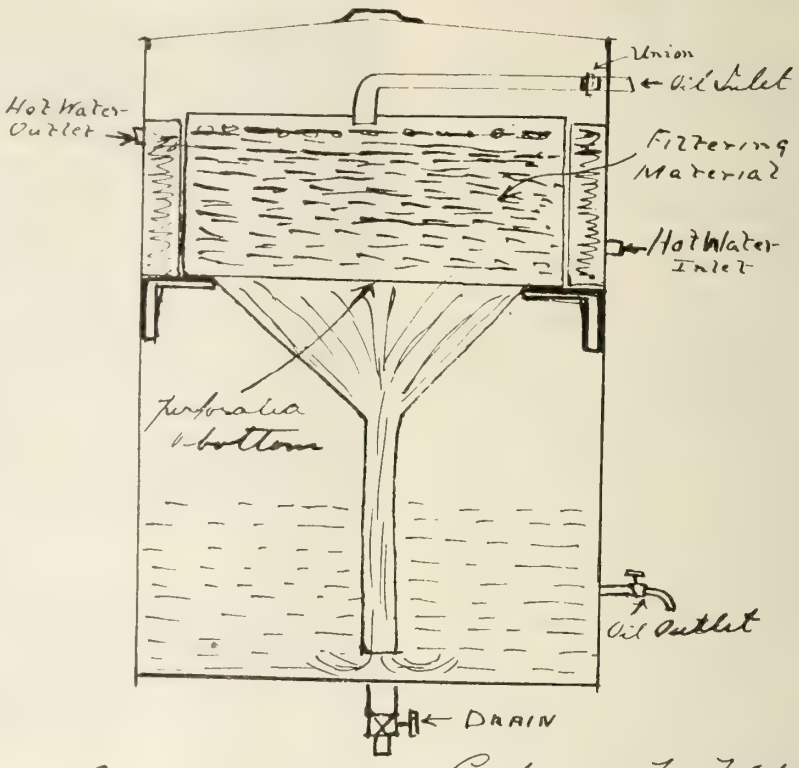
OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

OIL FILTER REQUIRED

Question:—Please tell me through the columns of "Power House" how to make an oil filter that will take the carbon and dirt out of cylinder oil that drips from the piston and crank shaft bearing of an open crank case gas engine. This oil does not contain any fuel oil such as might get into the crank case oil of a crude oil, or kerosene engine.

Answer:—There are a number of very efficient oil filters on the market, and it might be cheaper for you to buy one than to make one yourself. However, if you prefer to make one, a very serviceable one can be made from galvanized iron, in the manner shown in the accompanying sketch.



A loose cover as shown. Container for filtering material can be lifted out for cleaning. Hot water can be drawn from water jacket of engine, to keep oil in filter warm, allowing easy flow. Material can be #16 or #18 galvanized iron. Size according to quantity of oil. Filter can be set on iron stool, or on own legs, according to convenience. Charcoal, excelsior, or cheese cloth can be used for filter. Gauge glass may be fitted, but is not really necessary, and only adds to expense. A further screen can be placed at level of bottom of oil pipe if desired.

Sketch of Oil Filter.

COILS FOR COLD BOX

Question:—We have to install a box for cooling off chocolate after it is moulded. The cooling is accomplished by passing the moulds through a small room which contains refrigerating coils, the moulds being on an endless belt. There is an opening at one end in the wall of the room communicating with the hot moulding room, while at the other end there is an opening for taking the cooled moulds off the belt. The question is whether it is more efficient to use small diameter coils and a larger number to get the required heating surface, or a smaller number of coils of large diameter. Also where would be the best place to put a fan for circulating the air in the room?

Answer:—In deciding whether or not to use small diameter coils there is something else be-ide the efficiency of cooling surface to be considered. While the small diameter coils should give better intimate contact with the walls, or rather more of the gas being in intimate contact with the walls, and also because of there being a rather higher velocity than with the large diameter coils, there are other points that should not be overlooked. The space being rather restricted, the installation of smaller diameter coils with a greater number of joints, makes the possibilities of access for repair more difficult. The installation will also be more complicated, and on the whole, more costly. We should be inclined to recommend the installation of the standard type of coil for preference.

With regard to air circulation. We should be inclined to think that if the coils were installed on the roof of the building, with suitable gutters underneath to catch any moisture which falls at any time, a natural circulation would be set up. The warm air entering with the belt from the moulding room would have an upward direction, and would thus come in contact with the overhead coils, and be cooled off. It would then fall to the bottom of the room, on account of its greater density. Any moisture would be condensed on the surface of the coils, and the air would thus be dry, or comparatively so, as it descended. The constant admission of fresh warm air would tend to create a definite circulation. We should be inclined to think that a fan placed in the room would result in the cir-

(Continued on page 38)

Some Problems of Power Plant Design

SOME interesting figures were given recently by Mr. J. S. Thompson at a meeting of the Fife Mining and Engineering Society, in Scotland. It illustrates very well some of the problems connected with large steam power stations, and also indicates in which direction research is being bent to find a solution for the future.

In recent years we have heard a great deal about super-power-stations and of the necessity of scrapping all the existing stations in the country as being either obsolete or, at any rate, very inefficient. To scrap the whole of the existing power-stations in the country at one go would be sheer madness. Undoubtedly, many of these are badly situated, far from efficient, and too small to meet the demands in the districts which they supply. New power-stations will have to be erected on a much larger scale, existing stations in many cases will be extended, and some of these will in time become super-stations.

Many of the smaller stations are now seeing the advisability of purchasing power instead of installing additional plant. In such cases the existing plant may be worked up to its full capacity until the time arrives when the cost of upkeep and the inefficiency of the plant, compared with the newer and larger plant installed in the station giving the bulk supply, renders it advisable and financially sound to scrap the plant and take a complete bulk supply.

The position seems to be, therefore, that in future we shall find many existing stations not extending their generating plant, but buying in more and more of the power they require for distribution to their consumers, until in time they buy in bulk the whole of their requirements. At the same time, the more favorably situated stations will be extending their plant all the more rapidly, because in addition to having to provide for the power requirements in their present limited areas, they will be called upon to supply power for the areas supplied by the other stations gradually closing down. Alongside of this development, entirely new super-stations will be erected in favourable situations.

Hydro-electrical Plant

Considerable attention is at present being given to the matter of hydro-electric power stations, and it is quite likely that in the future a number of such stations will be constructed in this country. Provided that the capital cost can be kept down to reasonable figures, there is no question as to the advantage of making as full use as possible of the natural resources of the country, both in order to provide power as cheaply as possible and also to save the country's other great natural source of energy—viz., coal. Probably many people would be surprised to know the number of water-power plants already existing in this country. For the most part, however, these are of comparatively small power, and we may certainly expect to see a considerable advance in the use of water power on a larger scale in the near future. However, after making full allowance for the use of water-generated power, the fact remains that so far as our own country is concerned the bulk of the power will be derived from coal.

In speaking of the power requirements of the country, it is, of course, assumed that the whole of the power will in time be distributed and used in the form of electrical energy. It is, therefore, very essential that generating plant should be installed having as high a thermal efficiency as possible. In this connection it is rather disappointing that comparatively few of the existing electric power stations in the country have an efficiency of more than 10 per cent.—i.e., the heat value in electric current sent out from the works is seldom more than 10 per cent. of the heat value of the coal put under the boilers.

Prospective Saving

It is interesting to note that if all the stations had operated at the efficiency of the most efficient station—viz, 17.75 per cent.—there would have been a saving of something like 3,000,000 tons of coal. If an existing station can operate to-day at an efficiency of over 17 per cent., it is reasonable to expect that the new super-stations should show an efficiency of 20 per cent., and this alone is a very great argument in their favour, resulting, as it would, in an immense saving of coal, and consequently in reduced cost of power to the consumer.

The thermal efficiency of a power station using gas engines might be taken at 25 per cent., and had the electrical requirements of the country been much smaller, and had the steam turbine not been brought into being, there is no doubt gas engines of considerable size would have been largely used for the generation of electricity. If a gas turbine of anything from 5,000 horse-power to 25,000 horse-power, and as reliable in every way as the present-day steam turbine, could be brought out, not only would the inventor make his own fortune, but he would make it possible to do away with steam boilers, and would do much to bring about Dr. Ferranti's ideals and to bring in the era of cheap power, thereby rendering a great service to the world at large. Almost as great a boon would be conferred by devising some method of getting over the present loss in the condenser of approximately 60 per cent. of the heat value of the fuel used caused by cooling the exhaust steam and changing it back to water.

Meanwhile, we must carry on with large steam turbines as they at present exist, either burning coal direct under the boilers or treating the coal for by-product recovery and burning gas as fuel. It is possible that in the future we shall see more co-operation between gas and electricity undertakings, and it is quite likely that in power stations some boilers will be fired with coal, others with coke or a mixture of coal and coke, and others with gas.

Sites and Towers

For stations of, say, 250,000-kilowatt capacity, it will be of the utmost importance to secure suitable sites with plenty of ground available for extensions, for storage of fuel, ashes, etc., and—if carbonisation of the coal is to be a feature—for the storage and handling of the by-products. The site must be convenient for the delivery of fuel by rail, and preferably also by sea, river, or canal. Large quantities of water will be required for condensing purposes, and this is one of the essentials that will frequently be the deciding factor in fixing the site; the tendency will doubtless be to lay down the stations close to the sea, or alongside large rivers. It is not always a simple matter to lay down a large power station close to the sea; in fact, to harness the sea-water for condensing purposes is sometimes a very costly matter, and for the very large power stations we are considering, it will be no easy matter to find rivers large enough to supply the required quantity of water. If the bulk of the output of a station is required inland and remote from any large river, it will probably be found necessary to resort to cooling towers, wholly or in part, and it must be remembered that even where cooling towers are used, a very considerable amount of water will be required to make up the water lost by evaporation from the towers, in some cases as much as can be supplied from a good-sized stream.

A Typical Station

As an example, take a power station having a maximum load of 250,000 kilowatts and a load-factor of 50 per cent. The units generated per annum in this station will amount to 1,095,000,000 (fifty times the output of the Fife Power Company's station). If coal is used of a calorific value of 12,000 B. Th. U. per pound, and the station operates on a thermal efficiency of 20 per cent., the amount used per annum will be over 700,000 tons, or about 2,000 tons per day.

Allowing for only three weeks' supply of coal to be kept in reserve, storage will have to be provided for no less than 42,000 tons. The ash to be handled will be round about 200 tons per day, or 70,000 tons per annum. If carbonisation of the coal is part of the scheme, considerably more coal will have to be handled, probably 2,500 tons or so per day, or, roughly, at the rate of 100 tons per hour all the year round, or, say, 200 to 300 tons per working hour.

The quantity of water pumped into the boilers will amount to over 1,200 tons per hour. The water will be used over and over again, and allowing that 5 per cent. is required for make-up, a quantity of not less than 60 tons of pure town-supply water, or of chemically treated water will be required each hour. For condensing purposes, not less than 84,000 tons, equal to 19,000,000 gallons of water per hour, will require to be pumped from the sea through the condensers and returned to the sea, or from the river and returned at some point lower down the river; if cooling towers are used, probably a still larger quantity of water will be required to be pumped from the ponds under the towers, and, after passing through the condensers, returned to the top of the towers. In this case, to make up for the evaporation from the towers, approximately 250,000 gallons of water will be required per hour. Even to supply this will require a loch or stream of no insignificant size.

THE EFFICIENCY OF YOUR PLANT

By W. F. Schaphorst

How much of the heat in your fuel is utilized? How much is converted into work?

Nine times out of ten the burner of fuel doesn't know, and it isn't such a complex thing to solve either.

This chart will give the answer closely enough, though, and you won't have to do any figuring at all in arriving at the result. Just lay a straight edge across the chart twice and the answer is immediately found in Column E. The result may surprise you. Usually it is altogether too low.

For example, let us assume that you burn coal. The average heat value for coal is about 12,000 heat units per pound, and so we will use that figure in column A.

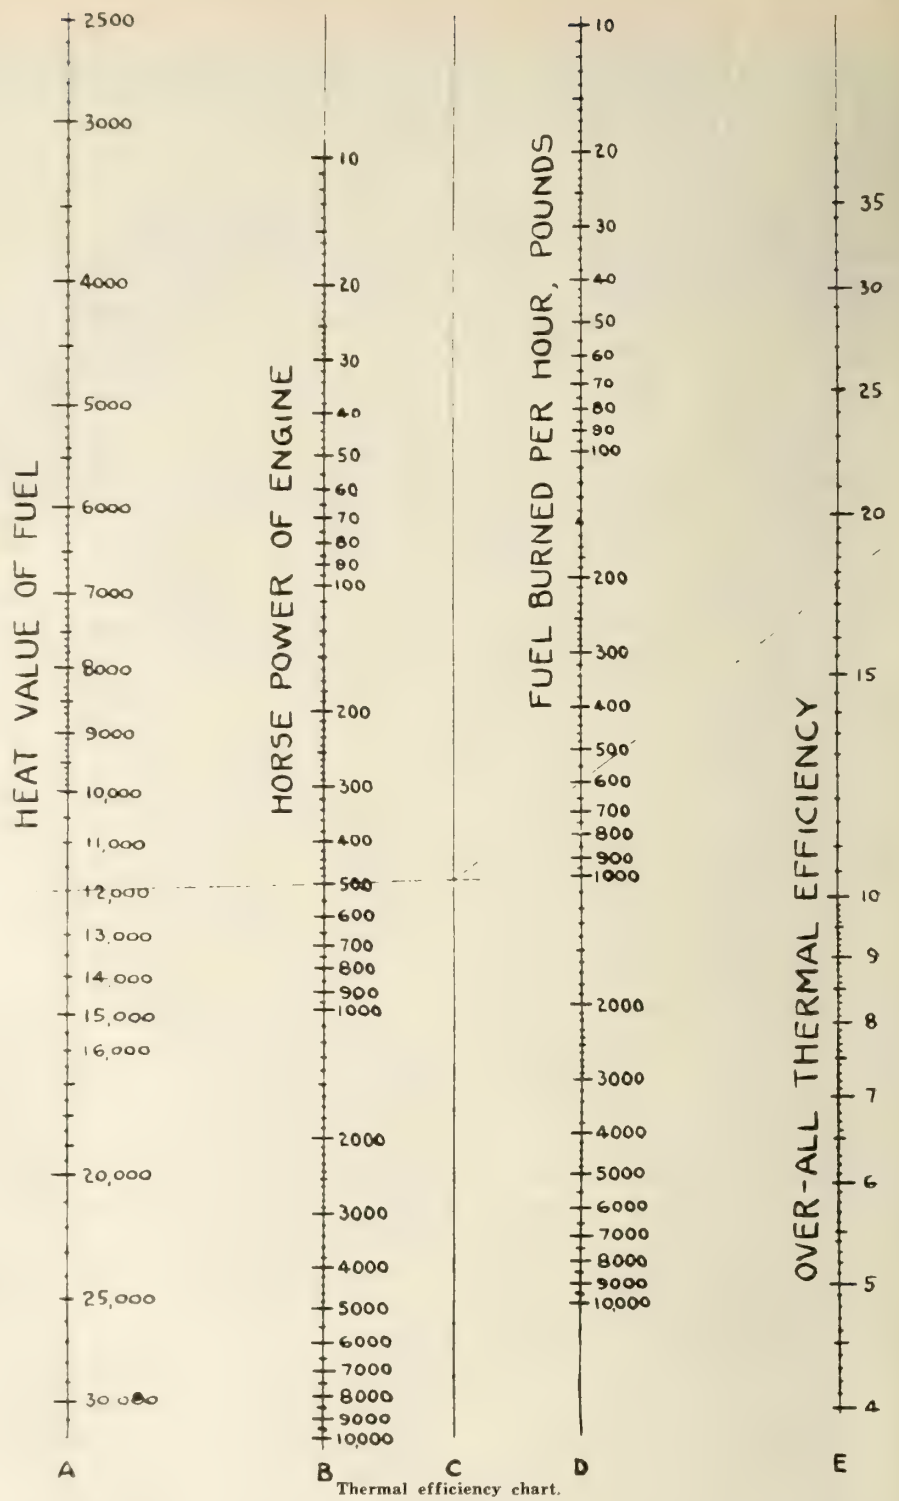
The horse power of your engine is, say, 500. See column B.

Run a straight line through these two points and locate the intersection with column C.

You burn, say, 600 pounds of coal per hour. See column D.

Run a straight line through the intersection in column C and through the 600 and the final intersection with column E gives the over-all 'thermodynamic efficiency" as it is generally called.

Therefore, in your plant, if conditions are as stated here, the performance is well above the average. Nearly 18 per cent. of the heat in the coal is converted into work. More accurately it is about 17.7 per cent.



Thermal efficiency chart.

The over-all efficiency is a thing worth knowing. If your efficiency is only 4 per cent. you should make an effort to increase it to 8 per cent. and cut your fuel bill in half. If it is 8 per cent., you should try to make it 16 per cent. and again cut the fuel bill in half. And so on.

Occasionally we find steam power plants where the thermodynamic efficiency is as high as 20 per cent., but such plants are entirely too rare. It is claimed that most plants operate at or under 4 per cent. I made 4 per cent. the minimum on this chart because such ridiculously low efficiencies should not be practised. I want to make this chart a stimulus for greater effort toward saving coal and other fuel.

The range of this chart is very wide—from 2,500 heat units per pound (green wood) to over 30,000 heat units. The heat value of fuel oils average at about 18,500 heat units per pound. Gasoline also averages at about 18,500.

Gas engines usually give higher efficiencies than steam. Efficiencies of nearly 40 per cent. are not uncommon with Diesel engines.

Practical Electricity for the Power Plant Engineer

Negative active material swollen and bulged.	Continued overcharging.	16
	Expanded from excessive heating.	18

(17) Climatic conditions cause overheating, likewise over-charging, impurities.

Overheating results in increased chemical action.

Warm weather calls for special attention to the battery, as evaporation is increased therefore pleenty of distilled water should be kept on hand for "topping up" the cells.

(18) Due to certain chemicals used in their construction, old negative plates sometimes have the active material swollen and slightly bulging from the grid.

Great care must be exercised in attempting to press back the active material, as abnormal pressure is likely to result in decreased capacity.

Negative plates in a charged condition must **Never be exposed to the air, as they rapidly oxidise resulting in such a rapid rise in temperature as to almost melt the grid.**

Care and Management of Power House Batteries

A great many people seem to think that a storage battery is something like a gas meter, and so can with advantage be stowed away in any old place, providing it is out of the way.

Happily however the "chiefs" of the large electrical power plants have now realised the necessity for a fitting location, specially designed to suit the conditions peculiar to storage battery operation.

The battery room should be lofty, well ventilated, bright. An exhaust fan should be provided to withdraw the fumes from the cells when on charge.

The floor of the battery room should consist of from 9 to 15 inches of good cement concrete. This should be covered with a thin layer of rock-mastic, or acid resisting asphalt. The level should so run that it drains into "gutters" running under each row of battery stands. The grids covering the down pipe to the drains should be made of earthenware, as the usual iron grids are soon eaten away by the acid.

The roof is preferably made of sound timber with a boarded ceiling but all the wood work must be painted with not less than three coats of anti-sulphuric paint. Never arrange a battery under a plaster ceiling as flakes of the lime wash are likely to fall into the cells, neutralising the acid, with consequent reduction of gravity, which in turn presents misleading diagnosis.

Arrangement of Cells

The cells should be arranged upon **single tier stands**, and in double rows down the length of the battery room. Do not place any cells against the walls. It is always an advantage to be able to work from both sides of a cell, in case of repairs, etc., especially if it is a large battery, whose elements may weigh anything up to 500 lbs.

If the cells are of medium size they will be in glass boxes; in such a case it is advisable to be so placed that the plates are at right angles to the length of the stands. In this position, when walking down a row, the attendant can see right through the cell between the plates.

For larger sized cells they should be contained in a hard-wood box (dovetailed not nailed). This box should be lined with not less than three pound chemically pure sheet lead. The box to be impregnated with anti-sulphuric paint.

A plentiful supply of good water should be laid on, with a tap inside the battery room, and a hose-pipe, so there is no excuse for not swilling the floor frequently and so preventing the accumulation of dust.

A sink should be fixed in one corner, for the personal convenience of the attendant, and for washing boxes, sections, elements, etc.

A first aid cupboard is most essential, with a generous supply of ammonia, linseed oil, lime water, cotton-wool, and antiseptic bandages.

A standing desk should be placed in a good light, with the manufacturers' instructions hung in front, whilst ample supply of forms, records, etc., should always be kept in the desk.

A small chest, containing portable testing set, voltmeters, hydrometers, thermometers, cell inspection lamps, graduated mixing glasses, test tubes, etc.

In the operation of the battery it is most important that either a recording-ampere-hour meter or an intergrating ampere-hour meter should be fixed in both the charging and the discharging circuits.

By such means only can you accurately ascertain the exact number of ampere-hours put into the battery, and the

number of ampere-hours taken out.

An essential instrument on the main switchboard is an automatic cut-out in the battery circuit. This is for cutting in the battery, and cutting out according to the conditions prevailing at the moment.

Never charge the battery by splitting it up into two circuits and charging both in parallel.

The dynamo for charging should always be shunt wound, as it is practically impossible for the battery voltage to run back through the exciting field of the dynamo, on account of its rising characteristic.

When the battery has been erected and about to receive its initial charge, great care must be exercised throughout this initial charge, as upon it, much will depend regarding the life and future behavior. A battery carelessly handled during its initial charge, will be ruined, and no subsequent treatment can undo the damage suffered at that time. Below are a few points to be carefully considered in connection with the initial charge.

(1) Fill up cells with electrolyte of the correct density.

(2) Fill up as quickly as possible, so that each cell is only standing in the electrolyte about a similar period of time before the current is switched on.

(3) Never interrupt the filling up, after once started.

(4) Temperature of electrolyte will increase when poured into cells. Do not start charging current until this temperature has fallen to about 75 deg. F.

(5) Go over all connections carefully. Make certain polarity of charging circuit is correct.

(6) Commence charging, at only **one half the normal charging rates.**

(7) Keep close tab on the temperature, taking readings every 30 mins.

(8) Immediately temperature exceeds 90 deg. F. reduce charging current by half. Should temperature continue to rise, stop charging entirely for about 2 hours, or until temperature has fallen down to about 75 deg. F.

(9) Take readings of specific gravity voltage, and temperature hourly for each cell.

(10) Plot voltage and specific gravity readings of one or two pilot (sample) cells. This will show up on the curve any abnormalities, and should be drawn to the attention of the manufacturer immediately. Keep these curves for reference.

(11) The initial charge may take from 72 to 95 hours of continuous charging.

(12) Somewhere within the above time limits, the gravity, and voltage readings will show themselves to be constant for a period of about 5 hours, no increase in either being indicated for such a period, voltage reading showing a constant 2.60 volts, and the sp. gravity 1.220 (or whatever working gravity is specified). Free and rapid evolution of gas from both positives and negatives. Only when such a combination appears can the battery be said to be fully charged.

One English authority says:—

"The first charge of a storage battery may be compared to the launching of a ship—it is the most momentous point in its existence."

Why the Battery Freezes

It has already been explained that the electrolyte in a storage battery is simply a mixture of sulphuric acid and water, and that the sulphur compound in the electrolyte, gradually leaves the electrolyte and impregnates the plates of the storage battery, whilst in the course of discharging, the further the battery is discharged, the more sulphur compound is abstracted from the electrolyte, leaving the density of electrolyte closer to that of water.

When this is fully realized it will immediately become apparent why precautions need to be taken during the winter to prevent the storage battery from becoming frozen.

Below is a table showing the various states of discharge and the temperatures at which the electrolyte will freeze.

Specific Gravity	Point of Charge	Freezing Point
1.280	100%	98 below zero
1.260	75%	60 below zero
1.225	50%	38 below zero
1.160	25%	zero
1.150	0%	13 above zero

When the battery freezes it is completely ruined and cannot be repaired, therefore special attention should be paid to the battery during the winter, whenever it has fallen to a condition of 1.225 or half charged, as any sudden snap of severe frost may result in the ruination of your battery almost before you are aware of the change.

In keeping a check on the discharged condition of your battery during the winter, it is important to bear in mind just how all operating conditions are changed during the cold weather, for example—

Engine works stiff.
Carburetion is slow.
Takes more current to start.
Days are shorter.
Lights required oftener.

Each of the above conditions result in greater amount of current being drawn from your storage battery.

The roads are generally more slippery in the winter, therefore you drive more slowly, consequently you do not put back the same amount of current as in the summer, therefore careful check must be made on the condition of charge in the battery.

Winter Storage

If it is not intended to use the battery during the winter it should be placed in winter storage.

There are two methods of winter storage.

(a) Wet storage.
(b) Dry storage.

Wet storage merely consists in keeping the battery in a cool dry place, keeping it clean, topped up with distilled water, and giving it a charge until the electrolyte "boils" once each month.

Dry storage consists of first fully charging the batery until it "boils." Adjust the specific gravity until it is equal in each of the cells. Then empty out the electrolyte, open up the cells and submerge the positive elements in a tank of cold distilled water, and the negatives in another tank of distilled water. Leave them in their respective tanks for several hours, until they can be exposed to the air without getting hot and smoking. Then store in a cool dry place.

The separators and the electrolyte must be thrown away, and fresh separators and electrolyte must be substituted when re-assembled in the spring.

The great advantage in dry storage over wet storage is due to the fact that all the elements in the battery are rendered inert. All chemical action is arrested during the whole period of dry storage, whereas during the whole period of wet storage chemical action is continuous. Therefore should this period extend over a period of say 5 months, the wet storage would have taken 5 months wear out of the battery, whilst the dry storage would have added 5 months to the life of your battery.

From a careful perusal of these brief articles on the storage battery, the author is hopeful that this important adjunct to the various scientific appliances which now enter so largely into our daily lives, will no longer remain that profound mystery, which has hitherto gained for the storage battery the alluring title of "The Black Box of Mystery."

MR. CARRUTHERS COMES BACK

Editor, Power House,

Sir:—Re Mr. Scott's "Dignified Protest" thanks for the caption, Mr. Editor, which goes a long way to show that you have no wish to see an East or West (in the question of a Dominion certificate), I beg to submit the following table in answer o his quesion "So why the dispartiy re the Ontario man?"

This is for the benefit of those engineers who, to use Mr. Scott's words "may attach some weight" to my letter in the July 20th issue on the Dominion certificate. Your notes re this same letter, Mr. Editor. merit some correction, but do not think it would do any good to forward you the proof, and am satisfied to leave the comparison of the table with intelligent engineers.

Cert. Alberta
3rd.—12 months firing.
2nd.—Above time, plus 24 months engineer 75 h.p. plant.
1st.—Above time, plus 12 months engineer 300 h.p. plant.

Cert. Ontario
3rd.—9 months firing.
2nd.—Above time, plus 12 months in charge of boilers.
1st.—Above time. No more steam service required.

The above table shows the steam serv-

(Continued on page 38)

Practical Method of Testing Centrifugal Pumps

Individual Tests Given to Each Unit—Proved Efficiency When Placed in Service—Interesting Method of Mounting Motor—Speeds Recorded on Vibration Tachometer.

DEFINITE characteristics of centrifugal pumps cannot be as accurately calculated in advance, as those of reciprocating pumps of various designs, and for that reason manufacturers usually prefer to test the former types before placing them in service. The reputation of the pump is thus guarded and at the same time statements, and guarantees as to performance, can be intelligently and confidently made.

Messrs. Darling Bros. of Montreal, manufacture a wide range of sizes of centrifugal pumps. Every pump is subjected to an individual test. To standardize results, and to make tests thoroughly and economically, a very interesting apparatus has been developed. Most of the impellers are bronze castings and practically all the pump casings are cast in iron.

It is not practical to machine some of the surfaces exposed to the liquids to be pumped, and in spite of the fact that the greatest care is taken in preparing the cores and setting them in the mold, small variations are found. This is only natural as molding can not be done to within a few thousandths of an inch. These variations are only infinitesimal but are reflected in the fact that capacities of the pumps vary slightly. For that reason this firm decided to test every centrifugal pump they built, and to do so in a very thorough manner under varying conditions. This would enable them to state with confidence just what every unit would do when placed in service.

Testing Appliance

The present apparatus was not designed, but rather developed from a basic idea. Improvements have been made from time to time, and now the apparatus is very complete. It is the intention of the firm to design a very complete apparatus from the data obtained in developing the original unit, which we are about to describe. The base consists of the bed of lathe. On one end of the base, or frame, is mounted a d.c. Allis-Chalmers-Bullock electric motor, which is used to drive the pumps to be tested. As the current supplied the factory is a.c. it was necessary to procure a source of supply of direct current. Nearby is located a belt driven d.c. Canadian General Electric generator of 6 k.w. capacity. The field rheostat of the generator, as well as motor rheostat, are located on the frame of the testing apparatus carrying out the idea of centralized control. At one end of the apparatus a switch board is located. This board carries the starter of the motor, an ammeter and a voltmeter.

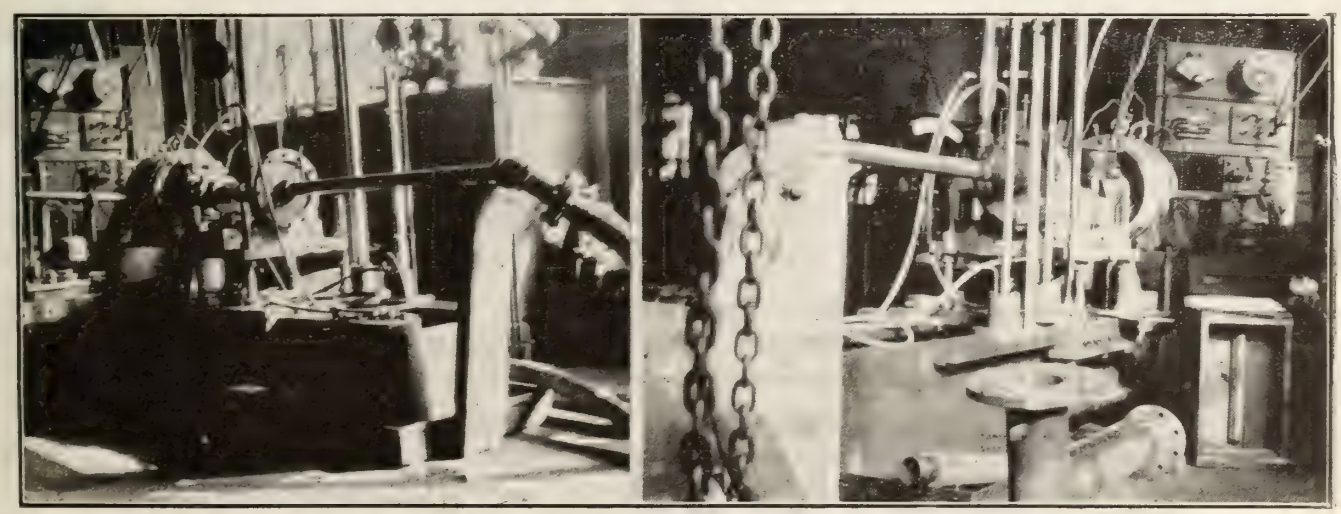
Unique Motor Mounting

The motor is mounted on the testing frame in a unique manner. It is held suspended at a fixed height in two bearing standards. The motor frame is free to rotate (on ball bearings,) about the centre line of the armature shaft. The armature is free to rotate with its shaft, independently of the motor frame, as in ordinary installations. The feet of the motor frame are in mid-air some eight or ten inches above the ways of the testing apparatus. A piece of 1 1-2 inch pipe is threaded into the side of the motor frame so that when the feet of the motor frame are in the horizontal plane, the pipe extends horizontally, at right angles to the centre line of the armature shaft, and with the axes of both pipe and shaft in the same horizontal plane. This arm is made to press on the platform of a very sensitive Toledo scales of the dial indicating type and originally designed for shell work. A special dial has been placed in the scales, reading pounds and tenths of a pound. An ingenious arrangement has been provided to take up the effect of any angularity of the arm. This is shown in Fig. 1. It might be mentioned that the effective length of the arm, measuring from the centre line of the shaft, is 31.416 inches, or ten times pi., which greatly facilitates calculations. The armature current is brought from the generator to two binding posts on the stationary standards which support the motor. The current is carried over to the frame of the motor, and thence to the brushes and field coils, (the motor being shunt wound,) by means of two conductors of brass wire cloth, which are very flexible and offer but infinitesimal resistance to the mechanical turning of the motor frame, which turning effort, or torque, is thus registered accurately on the scales.

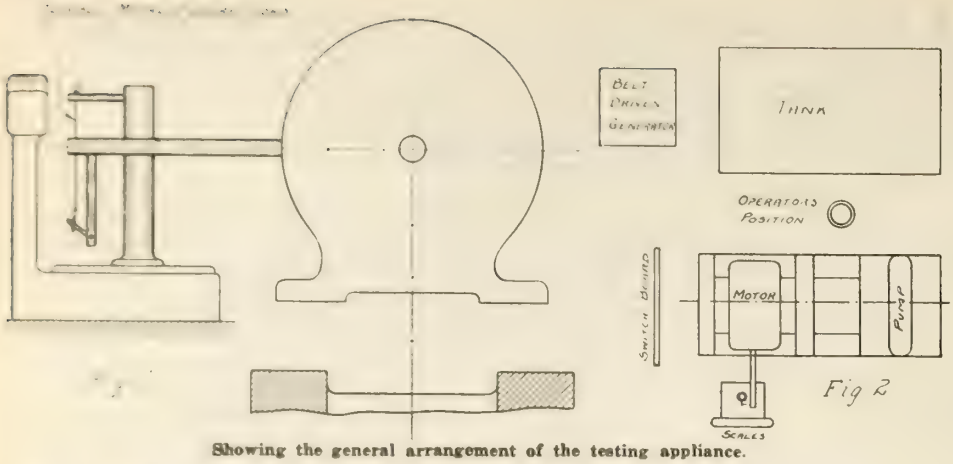
There are arrangements which provide for running the motor either way so that right and left hand pumps can be tested. Speeds up to two thousand r.p.m. are obtainable from the motor. The motor and pump speeds are recorded through the medium of a portable vibration tachometer.

Power Delivered

First impressions might suggest that the voltmeter and ammeter were used to determine the mechanical power delivered to the pump shaft. As electric motors operate at various efficiencies under varying load and speed conditions, this method would involve a new set of variables in the calculation and thus open up a new field for error. A characteristic curve of the motor would be necessary. To avoid these complications the ingenious and accurate dynamometer device is used to determine more directly the mechanical power delivered, without considering either mechanical or elec-



Two Views of Darling Bros.' Installation For Testing Centrifugal pumps.



Showing the general arrangement of the testing appliance.

trical efficiencies. The meters on the switch board are used largely to determine the loads on the motor and generator and thus guard against overloading. As before stated, the generator is a 6 k.v.a. machine, but when large pumps are being tested, a steam driven generator of larger capacity is used.

There is a flexible coupling on the motor shaft which is used to connect up to the shaft of the pump to be tested. The coupling also provides for the small amount of end play that it is desirable to have in the pump and in a motor of this type.

Locating the Pumps.

On the ways of the apparatus, toward the end remote from the motor, a sliding carriage is located. It presents a flat square surface and is gibbed to the ways. Provision for locking in any desired position is made. This longitudinal motion is used in locating the pump. Vertical adjustment is also provided. There are four threaded posts of generous cross section, located, one at each corner of the carriage. A platen is supported on these posts. Lock nuts above and below the platen permit of its adjustment to any desired vertical position. When a pump is being tested, the pump frame is bolted or clamped to the platen. The adjustments just described permit of the necessary movements required to line up the pump shaft with that of the motor.

Hydraulic System

The hydraulic arrangements are very complete. A 900 gallon steel tank supplies the water. It is open to the atmosphere. The suction pipe leads from the bottom of the tank. A complete arrangement of valves permits suction lines of desirable size to be coupled up. A combination of pipe and hose is used in nearly all lines for convenience in coupling up. A small hose is led off from the suction line to a mercury manometer, which indicates the amount of vacuum.

The discharge line is led to a 4 in. pipe header located near the ceiling. From the discharge line also a small line is taken, which line is led to a mercury manometer, which is graduated to read directly in feet of head and pressures, up to 70 feet and 30 pounds, resures a specially graduated pressure gauge is connected to the line, there being a small "T" in the manometer line and valves which would permit the cutting out of the manometer.

From the header into which the discharge is led, there are three pipes leading vertically down to the tank. There are two 2-in. pipes and one 3-in. pipe, each provided with a Venturi tube. One 2-in. pipe has a 2-in. x 23/32 in. throat, the second 2-in. pipe has a 2-in. x 1-1/16 in throat, while the 3 in. pipe has a 3 in. x 1-3/4 in. throat. Each Venturi tube is connected with a third manometer. Three scales are provided. These scales are removable and to read the discharge from any of the tubes it is only necessary to place on the proper scale and to cut out the other tubes. This is easily done as valves are provided. The discharge can be made through any one of the three tubes, or any two, or all three can be used at once. To get the total discharge in the case where more than one tube is used it is necessary to read the discharge of each tube separately. The whole apparatus is so designed that an operator can remain at one point and control and gauge every part of the apparatus.

The device has been developed largely in the plant and at no small expense. The calculations are very simple and in most cases the data are read directly The only calculation is that of the power supplied. When this is figured, it is a comparatively easy matter to deduce all the data required. As variable velocities are possible, the action of pumps under a wide range of speeds can be obtained. Valves are placed in the lines so that the vacuum in the suction line can be varied, and also the discharge pressures by valves in the lines containing the Venturi tubes. Complete data of the performance of a pump can be obtained in a remarkably short space of time.

COILS FOR COLD BOX

(Continued from page 32)

culation of larger volumes of air than is necessary, thus throwing more work on the coils.

We have seen a cool room laid out in the manner described, except that in this case the chocolate was not carried through the room on a belt, but was laid out on tables. There were in addition a couple of men in the room from time to time, unloading fresh batches and removing the cooled chocolate. There is another advantage in having the coils on the roof, in that it leaves the floor of the room quite clear.

MR. CARRUTHERS COMES BACK

(Continued from page 36)

ice, in addition to shop time, required in the two provinces. The one year in charge of a 300 h.p. steam plant required by Alberta could not be secured by the local man unless he had a 2nd class cert., thus making his total steam service 4 years, compared to 1 year, 9 months in Ontario. Of course, this disparity "is only small talk," according to Mr. Scott and some others living in provinces where certificates are more or less easily obtained and will never be noticed when exchanged for a Dominion "Uniform" certificate. Mr. Scott's remarks re motor-driven air-compressors may apply in the east but not the west.

Yours truly,
J. A. Carruthers,
Master Mechanic.

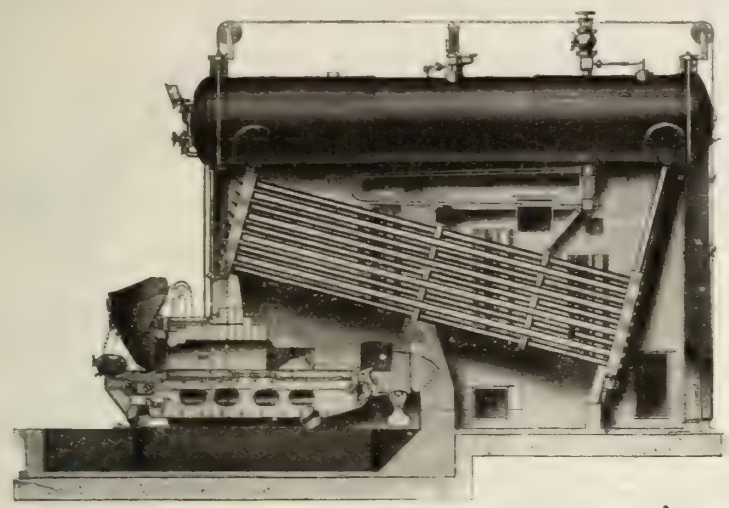
An aeroplane engine that will burn crude oil, and is no heavier than an ordinary gasoline plane engine has been developed by a British armament firm. It has six cylinders and capable of 750 horsepower.

MONCRIEFF'S "UNIFIC" WATER GAUGE GLASSES

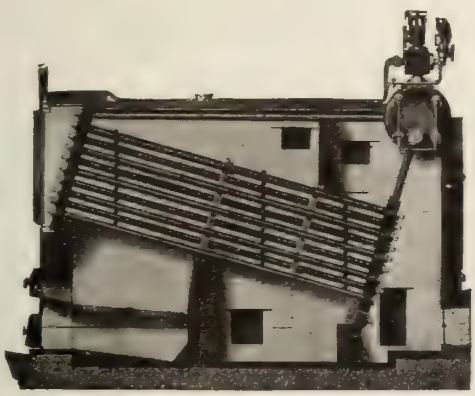
Moncrieff's "Unific" is not a cheap glass. But because it outlasts many ordinary glasses the "Unific" is economical British Made

The "Unific" does not readily corrode It resists extreme changes of temperature and withstands the highest working steam pressure.

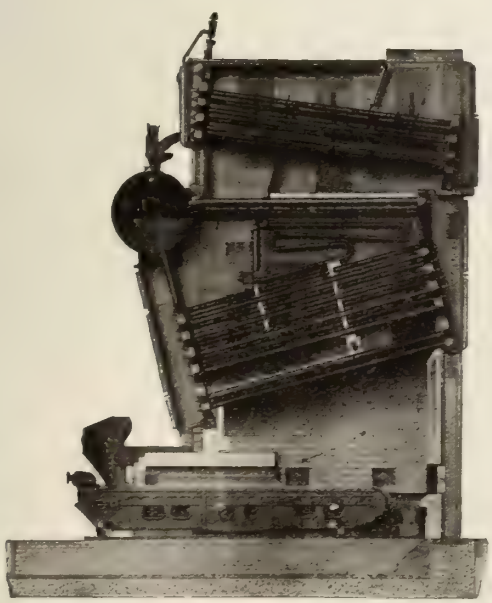
JOHN MONCRIEFF LIMITED
PERTH, SCOTLAND
Canadian Representative: W. J. WALL, 134-136 Bleury St., MONTREAL, CANADA



W. I. F. TYPE—With chain grate stoker and superheater suitable for most purposes on land.



CROSS-TYPE—A most desirable form of boiler where headroom is limited.



MARINE TYPE—(For land purposes). The marine-type boiler is equally adapted for installation on Land and is especially suitable for electric generating stations and other quick steaming plants. Where ground space is limited, and expensive, it offers particular advantages.

THERE IS A TYPE OF B. & W. BOILER

TO SUIT EVERY CONDITION ALL HAVING THE SAME PRINCIPLES OF CONSTRUCTION, VIZ:—

EFFICIENCY DURABILITY SAFETY

Water divided into sections, no general explosion can occur.

Every section able to contract and expand without interfering with any other part of boiler.

Boiler as a unit can move without disturbing setting.

Positive circulation of the water keeps all parts at nearly uniform temperature.

Proper workmanship.

Materials which experience has shown to be the best for the particular purpose.

A great excess of strength over legitimate strain.

No joints or cast metal exposed to the direct action of the fire.

Perfect circulation of both water and gases. Proper proportions for work to be done at any rating.

Ample water and steam capacity and water space for disengagement of steam.

Scale forming materials and soot can be removed while boiler is working.

All parts readily accessible for cleaning and repairs.

Adaptable to any furnace burning any fuel, solid, liquid or gaseous.

No restrictions to draft.

QUICK STEAMING.

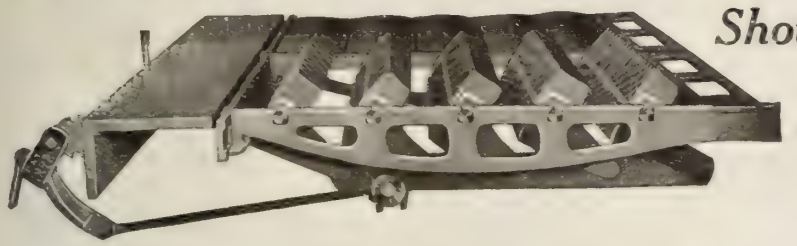
A Reasonable Saving of 5 to 10%

Should You Expect More?



WE GUARANTEE that with the use of CYCLONE SHAKING AND DUMPING GRATE any grade of hard or soft coal, **or screenings of same,** can be burned with excellent results both as regards Economy and Capacity; that the total annual expense to the user for coal, interest, depreciation, repairs, damage to boiler, liability of shut-down, etc., will be much less than would be the case with any other type of Grate or Stoker on the market.

The Canadian Steam Boiler Equipment Co.,Ltd.

Sole Makers for Canada

20 McGee Street PHONE: G. 3660 Toronto, Ont.

POWER PLANT EQUIPMENT

New and Used—

Equipment that shows clearer than words the Petrie policy of quality, service and satisfaction.

Firebox Boilers
12 H.P. to 150 H.P.

Horizontal Boilers
15 H.P. to 200 H.P.
Marine—Internal Fired

Tanks—Any Size, Any Capacity

Vertical Boilers
1 H.P. to 75 H.P.

Vertical Engines
2 H.P. to 75 H.P.

Automatic Engines
6 H.P. to 450 H.P.

Horizontal Engines
5 H.P. to 250 H.P.

H. W. Petrie, Ltd.

Toronto and Hamilton

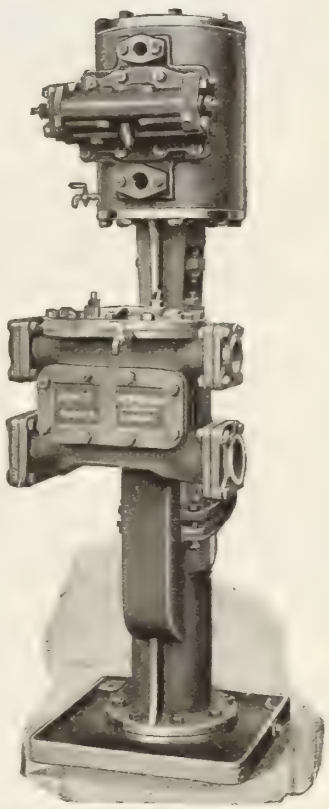
FULL LENGTH Strokes At All Speeds

Although these pumps are double-acting, one of the usual two Ram Glands is dispensed with, reducing the vertical dimensions to practically those of vertical piston pumps. A brass sleeve protects the ram from all dust and ashes.
In cases where the work is variable

HEPBURN Patent Vertical RAM PUMPS

will run at a very slow, as well as at normal speeds with reliability and will maintain their full stroke under any circumstances.

Write for further interesting features.



JOHN T. HEPBURN, LIMITED

Engineers and Iron Founders

18-60 VAN HORNE ST., TORONTO, CANADA

A Striking Message

A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. Here is the letter:

"I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. **This is a mistake on their part,** but for all I know to the contrary it may be due to the lack of energy on the part of the Power House ad. manager in getting after them. **It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages so much as on the ADVERTISEMENT PAGES."**

POWER HOUSE
Solves the Problem

It is a dominating factor in maintaining power plant efficiency in equipment and service.

Every issue teems with advertising and editorial matter of a character that will keep YOU right up to the minute in power plant knowledge.

TWO ISSUES PER MONTH
TWENTY-FOUR PER YEAR
TWO DOLLARS

SITUATIONS WANTED

STATIONARY ENGINEER — SECOND CLASS, requires position, ten years' experience of steam generation, refrigeration, cold storage and electric generation, thoroughly experienced with heating systems and hydraulics and all classes of stationary engines, used to large plants, good references. Apply to Box 5122. P.3H.

FOR SALE—FLUE GAS THERMOMETER, Vapour Pressure Type. Range 0 to 1000 degrees Fahrenheit. Dial 8" Diameter. Complete with 15 Ft. of Flexible Tubing. Price $25.00. Write Power House, Box 150.

STATIONARY ENGINEER, SECOND-CLASS, requires position; thoroughly experienced in operation of heating, refrigeration, compressed air, and knowledge of electricity, as applied to institutions. Can handle switching locomotive. Apply Box 109, Power House. P.1.H.

FOR SALE

JARDINE AND TOLEDO PIPE THREADING tools; also blacksmiths', machinists' and boilermakers' tools; get a catalogue and specify your needs; it pays to use the best tools. A. B. Jardine and Company, Limited, Hespeler, Ont.

When answering this advertisement, mention this paper. P.F.H.

ONE 12-TON WATEROUS 3-WHEEL STEAM roller; first-class condition; $3,600.00; Toronto delivery.

WILSON-McGOVERN, LIMITED, LUMSDEN Building, Toronto.

When answering this advertisement, mention this paper. P.F.H.

H. W. PETRIE, LTD., 131 FRONT STREET W., Toronto, sell new and used boilers, engines, air compressors, electric motors, machine tools, wood-working machinery, transmission equipment and small tools; get our prices for machinery on monthly rental.

When answering this advertisement, mention this paper. P.F.H.

Every Engineer, Mechanic and Electrical Worker will welcome this new master set. It will answer your problems.

It will help you with your daily work.—A sure source of advancement and higher pay. Complete up-to-date information that is thoroughly and easily explained on every branch of modern engineering and electrical practice.

AUDEL'S ENGINEERS & MECHANICS GUIDES

4750 PAGES • **$1 A MONTH**
8754 ILLUSTRATIONS **$12 COMPLETE**

These Guides tell you all about—

Theory, Practice and Operation of ALL Steam Engines; UNIFLOW and POPPET VALVE ENGINES, and LOCOMOBILES, Locomotive-Marine Engines; Turbines; Rotary Engines --the Indicator -- Lubrication -- PRACTICAL MANAGEMENT. GAS, GAS ENGINES--*Aeroplanes* and *Aviation*--HOW TO SELECT AN ENGINE. STEAM ENGINE rules and formulae. Steam Boilers; Heat-Combustion; Fuel and Flue Gas Analysis-C02 Recorders-Construction of all types of Boilers,--Mechanica Stockers--Oil Burners--Setting--Chimneys--Mechanical Draught --HOW TO SELECT A BOILER--BOILER DESIGN based on A.S.M.E. BOILER CODE--OPERATION FIRING. Pipes, Fittings--Heating and Ventilation--Refrigeration--Cooling Towers --Condensers--Distilling Apparatus--Elevators--Cranes--Ropes and Cables--Splicing--*Practical Electrical Engineering* as an aid for engineers and electricians in obtaining a license--ready reference index, covering entire field of Modern Electricity.

SHIPPED TO YOU FREE

Not a cent to pay until you see the books. No obligation to pay unless you are satisfied. Send coupon now--today and get this new master set for engineers. Pay only $1 a month.

SEND NO MONEY

THEO. AUDEL & CO., 72 Fifth Ave., N. Y.

Please submit me for approval, AUDEL'S $10,000 MASTER SET FOR ENGINEERS & MECHANICS. Ship at once prepaid, the 8 numbers. If satisfactory, I agree to send you $1 within 7 days and to mail you $1 monthly until $12 is paid.

THIS ENGINEER KNOWS

He can't keep down costs when he depends on guess work. Guess work means WASTE.

You will never know unless you measure the flow in your process lines whether you are eliminating WASTE.

Correct checking is the only true way to operate your plant efficiently.

The CORY-ROYER FLOW INDICATORS have made it possible to effect great SAVING in Fuel, Gas, Steam and Water consumption.

LET US TELL YOU MORE ABOUT IT.

Write to-day.

Impossible--

for any water tender to follow every change in boiler water level, and instantly do the right thing.

But that is exactly what the COPES Regulator does—watches every move of the true water level and makes the correct change in feed, automatically.

When the load suddenly drops, the COPES instantly increases the feed water, thus storing the excess furnace heat. The COPES reduces the water input over every sudden peak, so that the stored heat can be used.

The COPES responds to changes in the true water level. It acts instantly, without lag—but is not affected by the sudden momentary changes in apparent level, without actual change in water volume.

The Copes does its work practically without attention

[illegible] to wear out to parts to need frequent [illegible]. The Copes has no springs or diaphragms; [illegible] Nothing but a heavy metallic [illegible] controls the opening of a perfectly balanced valve, according to changes in water level in the boiler.

The methods—and the savings in fuel and labor—are fully described in our new Catalog D. Sent gladly on request; write us for it.

5 Retort RILEY STOKERS installed under 487 H. P., G. & McC. boilers.
Smith, Hinchman & Grylls, Consulting Engineers, Detroit.

More Steam at Lower Operating Cost

THE PROBLEM.

At the plant of Hiram Walker & Sons, Ltd., Walkerville, Ontario, more steam was required. Their boiler room contained 10—125 H.P. boilers. These boilers were economically fired but the plant layout in general was inefficient.

THE SOLUTION.

They replaced these *10* boilers with *3* of 487 H. P., fired by Riley Stokers which now gives them ample steam capacity. Although the normal boiler H. P. is increased but little the *actual* capacity is about three times greater because the Riley Stokers will operate the boilers up to 250% of rating or more. *When the above picture was taken two of the boilers were making 200% of rating.*

THE RESULT.

Greatly increased capacity with a *reduction in operating expenses.* The improved power plant layout with automatic coal and ash handling equipment and Riley stokered boilers has made possible a reduction in labor from 8 men to 2 men per shift. This saving in labor alone amounts to nearly $100 per day.

Find out what the Riley can do for you.

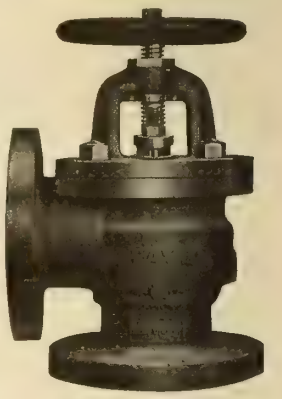
"Beaver" Non-Return Stop and Equalizing Valves

are the engineers' choice due to their records for trouble-free performance.

This performance is obtained by simplicity and proper construction.



In the Beaver Non-Return Stop and Equalizing valve the moving parts are cast and machined in one piece, being absolutely true to begin with and having no screwed connections to work loose and cause the valve to stick, due to the parts getting out of adjustment. The bronze dash pot is hung from the top, giving freedom of expansion.

The yoke makes a metal-to-metal joint with the body, no gasket being used.

An important feature in the design of valve is the areas through the body and seat and in this particular liberal allowance has been made in the construction of "Beaver" Valves. At no point are they cramped, nor will they obstruct the free flow of steam or water, the areas being in excess of the nominal diameters of the connecting pipes, yet the valves occupy a minimum of space.

The stuffing box gland being made of bronze offers a non-corrosive surface for the stem and also prevents the gland breaking when the stuffing box is being packed.

"Beaver" valves are designed for a working steam pressure of 250 lbs. per square inch and are subjected to a hydraulic test of 500 lbs. per square inch before leaving our factory.

All of the wearing parts can be renewed, should they become worn or broken.

"Look for the Name"

PENBERTHY

Automatic Cellar Drainer

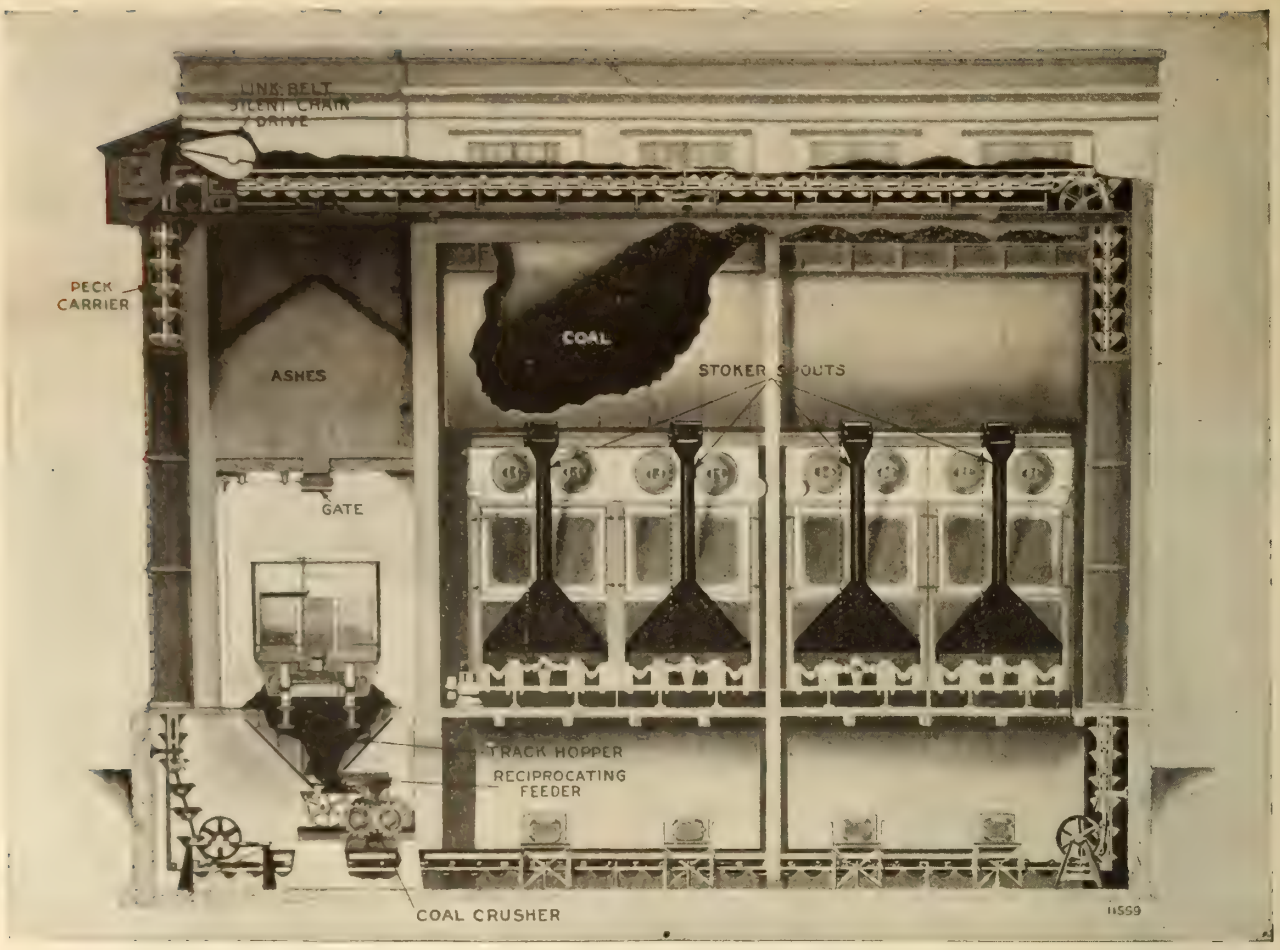
THE PENBERTHY Automatic Cellar Drainer is a Penberthy water pressure ejector of high capacity, automatically operated by a float-controlled, quick-opening-and-closing valve C. This valve is never partially opened—it cannot leak. The float arms are slotted at A, which prevents the ejector from operating until the water has raised the float up to the highest point. This allows the machine to work for longer periods and not so often, thus preventing considerable wear and the leakage and dribbling of water, so common in the majority of drainers.

For the purpose of compactness the float is flat on the top and is built around suction pipe B, ensuring perfect rigidity. All working parts, except the strainer and float, are above water. The special strainer H is so constructed that the water is drawn in at the sides so that sediment is undisturbed by suction. A foot valve inside the strainer instantly closes when the drainer ceases to operate, holding the pipes ready primed for the next filling of the sump.

Send for Catalogue on: Cellar Drainers, Injectors, Ejectors, Lubricators, Valves, Grease Cups, Oil Cups, Gage Cocks, Water Gages, Air Cocks, Whistles, etc.

MANUFACTURED BY

Penberthy Injector Co., Limited, Windsor, Ont.



A Typical Boiler Room Equipped With the Peck Carrier for Handling Coal and Ashes

ONE UNIT FOR BOTH COAL AND ASHES

DO you know that there is one efficient, sturdy and dependable machine which solves the entire problem of handling coal and ashes in boiler houses? It has been adopted as standard in hundreds of plants throughout the country.

This illustration shows how it is done with the Peck Carrier.

Is not so important a subject worth study by everyone who handles coal and ashes?

We can furnish you in convenient form whatever further information you may want or if you prefer to talk to one of our experienced engineers, you have only to say so.

The Valve Value of the Century

These standard valves embody the following special features: (1) made of virgin metal, high in copper content, and of great density and steam resisting strength; (2) swivel disc spindle, bearing in center only; (3) extra long stuffing gland, giving the effect of a union bonnet; (4) large hexagon with ample clearance for wrench surface; (5) latest model barrel type body, exceptionally strong; (6) shut-off seat-valve can be repacked when open; (7) special packing of great steam resisting qualities — valves can be repacked under pressure.

Mueller Globe and Angle Valves

excel because of the above seven points of supremacy. They are competitive only in price. They lead in value and in dependable service.

Made in all sizes from 1/8" to 3" inclusive. Write for full description and prices. Mail orders given prompt attention.

C S C Vertical Self-Oiling Engine. Over 15,000 of these units are in operation throughout the country.

Engine Meets With Approval of All but The Night Watchman

In a certain power plant there is a CSC Vertical Self-Oiling Engine that is operating 24 hours daily—giving dependable, economical performance—assuring continuous service without delays.

This engine received the commendation of the superintendent, the engineer, the plant manager—all except the night-watchman. He complained that the engine ran too quietly—that he was required to make too many trips to the engine room only to find that the CSC Engine was operating faithfully.

If you require an engine for auxiliary drive we will gladly send you complete information regarding CSC Engines and will refer you to plants in your locality where these units have given never-faltering, economical service over a long period of years.

They'll Stand Rough Usage and Careless Handling

SELCLO GLOBE VALVES

Selclo Globe Valves are made to stand the strain of extra severe service.

On steam, water or special service lines where valves are repeatedly opened and closed Selclo Valves give long and trouble-free service.

Selclo Globe Valves are especially suited to factory, shop and railroad roundhouse work where the service is exceptionally severe and where very often inexperienced people have occasion to operate them.

The Selclo Globe Valve is particularly recommended for use on vertical steam lines where condensation accumulates, as pressure being above the disc assures the valve being tight at all times.

Write for descriptive literature giving full particulars.

SINCE 1864

Detroit V-Type Stokers for the Public Schools

The popularity of Detroit V-Type Stokers in the public schools bears witness to their value from an investment standpoint, for all natural draft furnaces —whether under fire tube or water tube boilers.

Detroit V-Type Stokers are money-makers in schools, public buildings, industrial plants—and wherever used. With them: (a) average overall efficiencies of 70-75 per cent may be maintained, (b) operator can fill coal hoppers and then attend to other duties, (c) cheaper grades of fuel can be burned than with hand firing.

Hundreds of schools have been equipped. Here are just a few:

Ashtabula High School, Ashtabula, Ohio
Baldwin School, Pontiac, Michigan
Cass Technical High School, Detroit, Michigan
Cleveland Heights High School, Cleveland, Ohio
Crosby High School, Waterbury, Conn.
Dewey School, Flint, Michigan
Colored High School No. 174, Washington, D. C.
East Boulevard School, Cleveland, Ohio
East Dennison School, Cleveland, Ohio
East High School, Cleveland, Ohio

FRICK Combined Refrigerating Machine

This machine fills the needs of dairies, groceries, meat markets, restaurants, hospitals, confectionery and floral shops, etc., for a simple and efficient small refrigerating plant.
The machine is manufactured in one ton and two ton sizes. It is a complete self contained unit, including compressor, condenser, separator, receiver and connections mounted on one solid portable iron base as shown. It is completely assembled in one crate with motor and motor base in separate box, and can be taken through a 26-inch door without uncrating.
No foundation is required. The machine is as easily put in place as the ordinary counter or refrigerator, and as easily removed—an important feature to the user who rents his place of business.

Machine is completely protected with safety devices. Either part automatic or full automatic control is supplied as desired. It is unusually quiet in operation and can be placed in any desirable location.

Ask our nearest distributor for further details and prices.

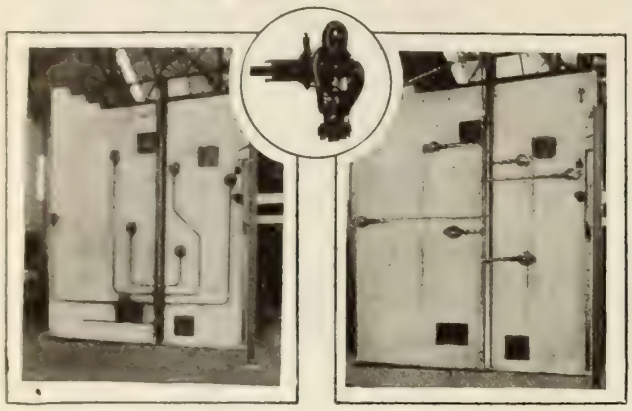
Diamond Valv-in-Head Soot Blowers Save Two-Thirds Material Required for Installation



With the independent valve soot blower system above there is required 66 feet of pipe for connections to individual units, and six 2 inch globe valves.

With the Diamond Valv-in-Head System above only 23 feet of pipe is required to connect the units with the main line. All individual control valves are eliminated.

With the Diamond Valv-in-Head soot blower system it is possible to save approximately two-thirds of the cost of material required for installation with the independent valve soot blower system. There is an actual saving in pipe of two-thirds, a considerable reduction in the number of fittings and the complete elimination of individual control valves.

On a typical 6 unit installation the bill of material for the independent valve system comes to $195.48, with prices as of October 1st, 1922. With the Valv-in-Head system the complete bill of material amounts to $64.28. The saving effected is $131.20. (Note: Comparison made between bronze body valves with nickel seats and discs for independent systems and Monel trimmed Valv-in-Head.)

This saving in material alone bridges a long part of the difference in cost between the Diamond Valv-in-Head and the independent valve soot blower. Other Diamond Valv-in-Head economies include: a saving of 50 to 60 per cent. in steam for operation; a saving of 50 per cent. in labor and a reduction in annual maintenance charges of 25 to 50 per cent. or more. Remember that Diamond blower elements used in the hot passes of water tube boilers are protected from oxidation at high temperatures by being CALORIZED.

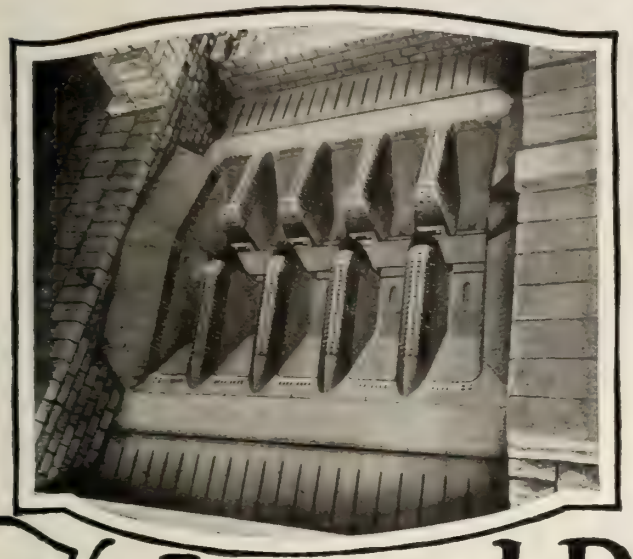
Announcing—



the greatest advance in stoker building

The Lateral Retort Stoker

TRADE MARK

MULTIPLE retort efficiency with single retort simplicity —that is the gift of the Lateral Retort Stoker to the power plant world.

The view above shows how the multiple retort effect is obtained in an extraordinarily simple way. Coal is fed lengthwise into the main retort by the strokes of a steam operated ram. It is then distributed sidewise into the several lateral retorts. Only two steam cylinders and moving units are used, and the few moving parts are never subjected to the heat of the furnace—yet note how this firing method attains a degree of efficiency never before equalled in a stoker of equal simplicity.

The coal is under-fed throughout. Although a side dump is employed, the fuel is not over-fed on to side grate bars as in former side dump stokers. It is under-fed, not only to the main retort, but also to each lateral retort. The advantages of under-feed combustion are retained—distillation of volatiles is slow and thorough; coking is complete. This insures highest combustion efficiency, and the large reserve fuel capacity of the retorts insures heavy overload capacity and ability to handle sudden peak loads.

The coal feed to the main cylinder and to the lateral retorts is controlled separately, insuring an even fuel bed and increased flexibility.

By applying the multiple retort principle to a side dump stoker the necessity for excavation and basement ash pits is eliminated. This makes the installation cost extremely low. Also it makes the stoker adaptable to old boilers without making expensive changes. How extreme simplicity, made possible by this revolutionary basic principle, has produced a high duty multiple retort stoker that can be installed at a moderate cost is told in a new catalog. Write for it.

The NASSAU POWER PLANT

of the

Canadian General Electric Company

At PETERBOROUGH, ONTARIO

This plant was constructed in connection with the reconstruction of the Nassau Dam by the Department of Railways and Canals. The first unit of the plant was put into operation in March, 1922.

The entire sub-structure of the Power House, including the forebay walls and draft tubes, is of concrete. It being essential that hydraulic losses should be reduced to a minimum, the draft tubes were finished with very smooth surfaces and well rounded corners.

The up-stream wall of the Power House is also the breast wall, and the interior of this wall is "bone dry," notwithstanding the pressure of the full head of 18 feet of water on the up-stream side. This result was obtained without the use of any water-proofing materials, which furnishes evidence of the value of concrete construction wherever a water-proof structure is required.

The Power House sub-structure was carried out in conjunction with the reconstruction of the Nassau Dam by the engineers of the Department of Railways and Canals, to the designs of Walter J. Francis and Company, the Consulting Engineers for the Canadian General Electric Company.

CONCRETE
FOR PERMANENCE

We maintain a Service Department to co-operate in all lines of work for which concrete is adapted. Our library is comprehensive and is at your disposal at all times without charge.

On the way to the convention of State Navy Engineers last year, the subject of this advertisement was one of many subjects discussed. Read below whether we have proved an emphatic "Yes" to the question.

Can you run a plant on one sheet packing?

WHEN Johns-Manville in their packing standardization propaganda said, "One sheet packing for all conditions," many engineers told us it couldn't be done.

On the face of it, they seemed right. To expect any one material to pack against such widely different conditions as air, steam, water, oil and chemicals was beyond all experience.

But now the only doubters are those who haven't tried Johns-Manville Service Sheet.

In thousands of plants Service Sheet is the one packing used for every sheet requirement, including the most severe.

That fact can stand by itself. An hour's debate would not make it any truer or less true.

How this saves you money

To stock one packing instead of many is, obviously, an economy.

You reduce investment in packing.

You save storage space.

You save the item of packing deterioration on storage shelves.

Some points of betterment

What is more, Service Sheet packs more satisfactorily than the materials it replaces. It is resilient—it will give to a temperature rise and come back without disturbing the joint. It is dense—and so a thinner sheet can be used, which means a stronger joint. It is durable—made of asbestos fibre and heat-resisting compounds, it withstands every wearing agent—and so obviates frequent replacements.

Rolling Mill Engine of 25,000 Horse Power

Built on Marine Lines, for the Hardest Kind of Land Service— Working at Full Power it Reverses Four Times Per Minute— Three Cylinder, But Not Compound

IN THESE days of steam turbines of ever-increasing size and power a reciprocating engine of 25,000 h. p. is something of an achievement.

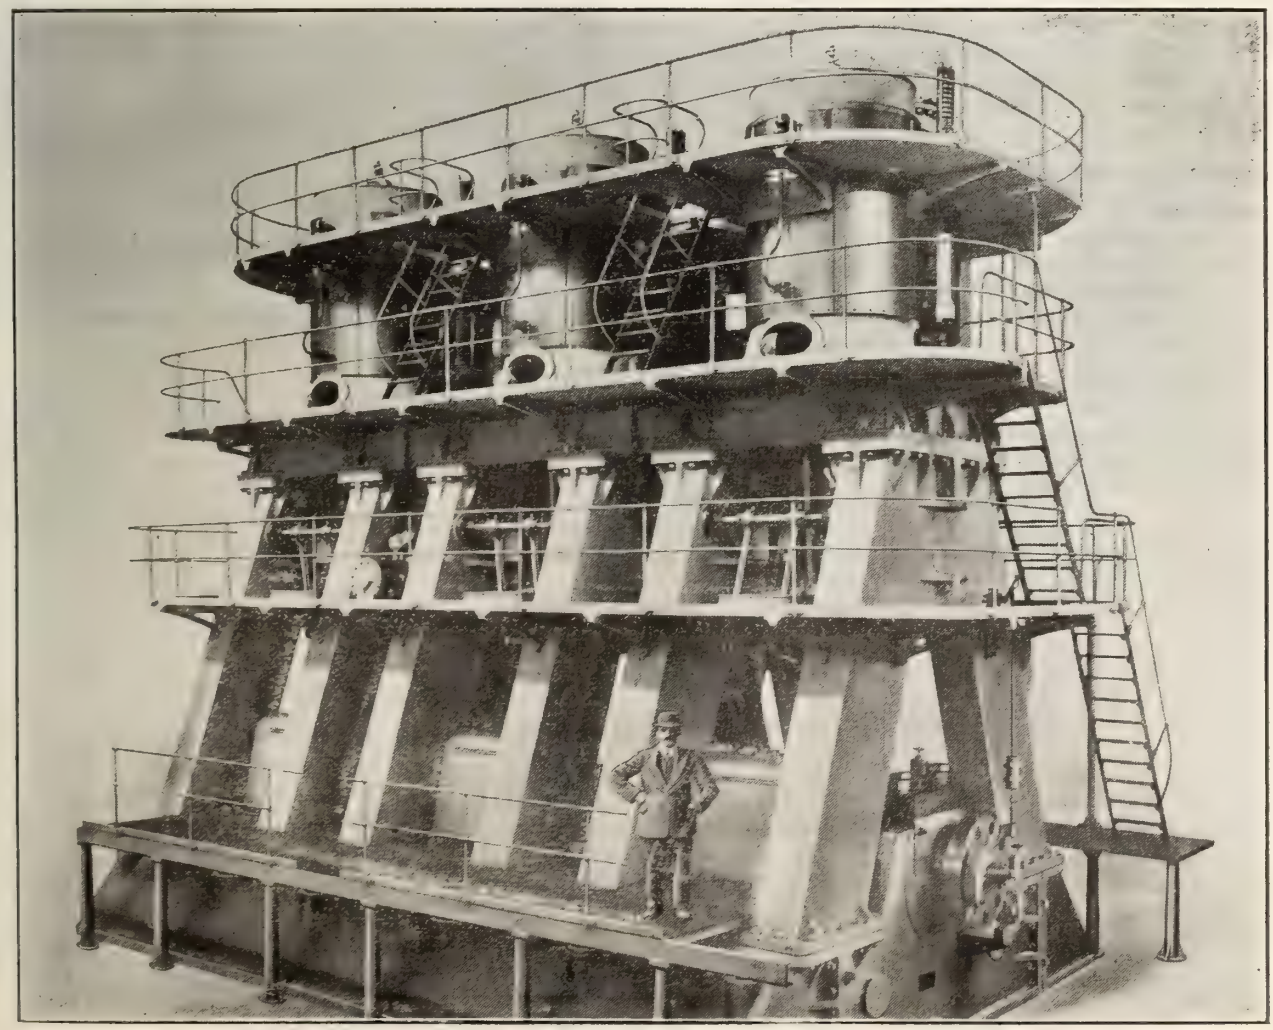
Such an engine was recently built for the Cargo Fleet Rolling Mills, which is one of the largest in England. It will be observed from the photos that it is built mainly on marine engine lines, so that it is not surprising to learn that it was built by a famous marine engine firm, Richardsons Westgarth of Middlesborough.

Not a Compound

There is no compounding in this engine, the three simple cylinders all taking steam at boiler pressure, 190 lbs., superheated 100 degrees.

The cylinders are 45ins. in dia. and have a stroke of 52ins.

This engine was built for speeding up the rolling of 24in. x 12in. steel joists, and other similar sections and it is required to reverse four times per



Front View of Engine.

minute, which is no mean performance in view of its size. The very heavy frame sections and the wide base were necessitated to give stability under this constant strain, the bed plate weighing some 105 tons and measuring 22 feet by 29 feet.

There are six main columns of the inverted Y type. These are made in two parts with a planed joint down the centre. In addition to the usual bolts the joints are specially strengthened by hoops cast on to bosses inside the joint.

The bearings shown on the column carry the main reversing shaft.

Valve Gear

The valve chambers are separate castings bolted to the cylinders, the valves being of the balanced piston type. They are 20in. in dia. and work in separate liners. Exhausting over the ends, these valves take steam at the centre through a 14in. double beat throttle valve placed close to them. The valve gear is of Joy's pattern, while the throttle valves are separately adjustable, although they can all be simultaneously operated by means of a steam-hydraulic reversing engine. The latter, of course, is essential in view of the heavy gear to be put in motion and the frequency of the operation necessary, and it is of the direct acting steam-hydraulic type very similar to that used on marine engines. The cylinder of this reversing engine is seen next the second column from the left.

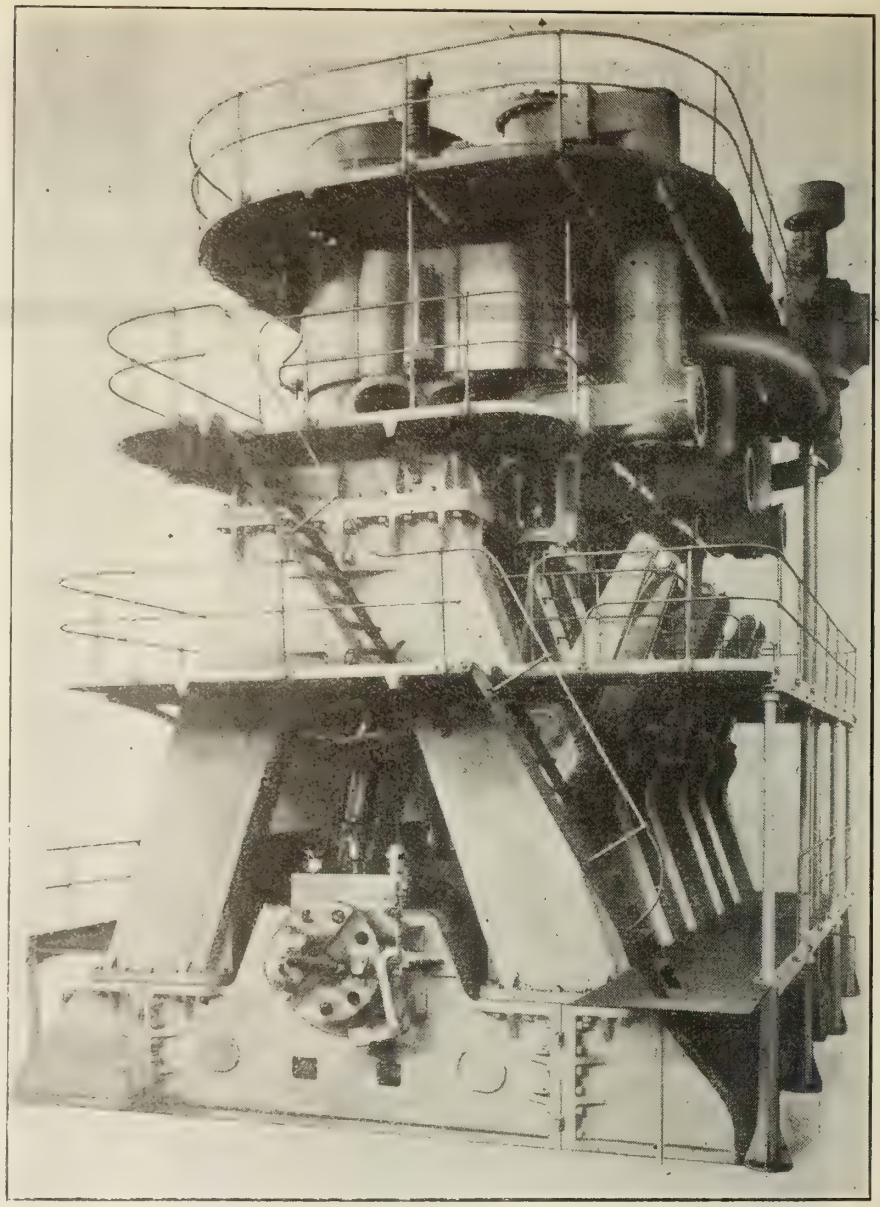
Built Up Crank Shaft

The crankshaft is built up of three sections, bolted together by flanges. Each of these sections consists of two webs and a pin forged out of the ingot, the two short lengths being shrunk on and pinned to the webs.

Both shafts and pins are hollow, being bored 5in. in dia. The body of the shaft is 22in. in dia. and weighs over 40 tons, but the whole was trued up in the lathe after being bolted together.

The main bearings are 24in. long and interchangeable. They are lined with white metal and water cooled. The connecting rods are of the orthodox marine forked pattern, the piston rods being 9in. in dia. and in common with the valve spindles are made of nickel steel. The pistons are steel castings machined all over. They rest on a collar on the rod, 8in. dia. steel nuts having a fine thread serving to secure them.

As ordinarily understood the engine has no governor but there is an emergency master valve in the main steam pipe. This comes into action when the normal speed of 140 r. p. m. is exceeded by 12% by means of a centrifugal weight on the end of which a trip level releases the hydraulic pressure which normally keeps the valve open.



End View.

Altogether the engine is an interesting example of a very powerful unit designed and built for exceptional duty. Needless to add in view of the very severe nature thereof everything had to be both simple and massive, while special facilities have been provided for inspection of the vital parts to be undertaken as easily as possible and any repairs effected with the utmost despatch.

The entablature which carries the three cylinders is built up of three castings two feet deep bolted together by deep flanges, the crosshead guides being also bolted to it assisting in tying the whole frame together. The cylinders themselves which have separate liners have cone shaped bottoms, forming little standards, inside which there is ample room for a mechanic to work at the stuffing boxes, the entry doors to which are seen just above the third platform.

A NEW CENTRIFUGAL PUMP

There are so many different types of centrifugal pumps in existence that it might seem impossible to invent another new type. Recently, however, a British firm introduced a special form adapted for marine purposes. In this service, owing to the rolling of the ship and to other causes, air is apt to be mixed with water in the suction pipe. The special feature of this new type, which is electrically driven, is that the air is first separated from the water, and afterwards both the air and the water are dealt with separately by properly designed pumps. When the water reaches the suction branch of the pump it is made to flow over a weir where most of the air is automatically released. This air is dealt with by a small reciprocating pump, while the centrifugal pump itself deals with the water. This pump has already been applied to motor ship service with conspicuous success.

Ladders and Stairways For the Power Plant

The Safety of Life and Limb Very Often Depends on the Proper Condition of Ladders, or Stairways—Some of the Principal Requirements of These Accessories Are Pointed Out

IN MEETING the needs placed upon the ladder, the character of material used in its construction varies from heavy angle steel or iron to a skeleton of wood—the degrees of permanency and the character of the load guiding in choice of materials and their fashioning.

Experience has dictated certain practices to be observed in building, placing, and using ladders The ladder should be of sufficient strength to resist safely double the strain of the heaviest load that will be placed upon it in use. This has been assumed to be about 450 lb.—the weight of a man and the burden he might reasonably be expected to carry up or down a ladder,—and a like weight added as a margin of safety. The ladder must be wide enough for the user to move freely and safely about his work.

A stationary ladder is one that is so anchored or fastened, permanently or temporarily, to a structure or piece of mechanism as to become a fixed part therefore. A portable ladder is one that is to be used transiently at various locations, and may have various forms, such as:—

A step-ladder so constructed as to be self-supporting; a sectional ladder of two or more sections so constructed that the sections will telescope one into another, or so arranged as to be united into a single ladder; a trolley ladder having a movement confined in permanent guides or ways at top or bottom, or both; a trestle ladder whose parts, each equivalent to a straight ladder, are hinged at the top to form A frames.

Clearances

In placing a stationary ladder, a continuous clearance space should be provided, back of the ladder rungs, such as to allow a man's foot to obtain a fair purchase on the rung, as a slight obstruction to the foot or hand in gaining a hold on a rung may cause a mis-step, with serious results. For this reason, general practice favors a minimum clearance of 8 in. and some authorities favor allowing a minimum of even 12 in. Continuous clearance space should be provided in front of the ladder, so as to allow a person to assume a free and natural climbing posture. Fixed objects projecting at random too close to the front of a ladder may strike and injure the person climbing, or they may catch the clothing of the climber and jerk him loose from his hold. To eliminate such a hazard, some requirements provide for a minimum clearance space of 24 in., but 30 in. to 36 in. seems to be more generally favored, because a workman often carries tools projecting from his pockets or tool belt that would not pass a 24 in. clearance. It is evident from the foregoing discussion that it is important to have a proper continuous clearance space of 15 in. on each side of the centre line of the ladder. If ladders are used as a common passage-way, provide one or more for ascending and another group for descending.

Material for Ladder

Permanent stationary ladders should be constructed of steel or iron and should be designed effectively to resist the impact blows of falling materials and loads swinging from cranes and hoists. Ladders having side rails and fastened top and bottom, with intermediary supports, are preferable to the built-in type consisting of U-shaped sections embedded in a wall or fastened to a shack. Side rails of angle steel or iron should not be less than ¾ sq. in. in cross-section, a size of 2 in. by ½ in. being preferred.

Ladders designed to reach safety valves, cut-outs, etc., where speed of operation may mean a saving of life, should always be of permanent type, securely fastened and constructed entirely of steel or iron.

Safe practices, applying to stationary or fixed ladders, include the following: When sections join, splice plates shall be of the same size and material as side rails, and carefully riveted or bolted. Wooden ladders may be spliced with steel braces of equivalent strength. Ladders over 20 ft. in length should be built in zig-zag sections and provided with safety platforms, no open space of over 18 in. being allowed back of the landing Brackets should be of suitable strength to support firmly the ladder and weight of workman and burden, and should be of sufficient rigidity to resist any anticipated impact from falling material or traveling crane. They should be fastened by through or expansion bolts firmly embedded in the wall, and should be spaced not over 12 ft. apart.

Temporary and portable ladders are usually constructed of wood, thoroughly seasoned long-leaf yellow pine, Oregon fir, or northern white spruce giving good results for side rails, and white ash, oak (second growth), or hickory for rungs. All material should be free from knots or shakes, although half-inch imperfections are sometimes allowable in side rails of the larger sizes of ladders if in centre of stringer.

The rungs should be designed as a simple beam supported at both ends to resist safely, without permanent or readily apparent deflection, the stresses incurred by a load equal to the weight of an average man imposed at the centre of the rung, plus any weight carried or supported by a man on the ladder. The minimum section of a rung should be a diameter that provides the most secure hand-hold. Having all the rungs in a ladder of uniform section is good, as it eliminates the annoyance of varying the grip with each rise. Rungs of a ladder should be free from splinters if wood, and burrs if steel, as experience has shown that it is such small annoyances to the climber that cause many a mis-step and fall; spacing of rungs should be uniform. General practice favors a string spacing varying 15 in. to 18 in., for metal construction a round steel or iron rung varying from ⅝ in. to 1 in. diameter, and for wooden construction a rung not less than 1⅛ in. in in diameter, and for wooden construction a rung not less than 1⅛ in. in diadiameter, tapered to fit a somewhat smaller socket. Excellent wooden rungs are made from blocks sawn to proper length. If of white oak, blocks may be split and hand-shaved to size and the ends machine-turned to fit sockets in stringers. Hickory or white ash will not split evenly and machine-turning will be necessary; consequently, careful selection should be made of material and careful inspection and testing made to avoid weak rungs.

Safety Bases and Tops

For wooden floors, metal points or lead-coated bases are recommended; for concrete floors, pivoted lead shoes or carborundum: for wet floors, recessed rubber bases have given the best satisfaction. For use on iron floors, carborundum has been found to serve very well, but Pennsylvania specifies the placing of an attendant at the foot of each ladder when working on iron floors. We cannot depend on any one type of base under all conditions and be safe.

Safety tops are provided for fixed ladders by omitting rungs above the highest work level, running the sides shoulder-high above that level. A "goose-neck" permits a higher degree of safety. Oilers' ladders, with hooked tops to fit over shafts, are becoming more and more the rule.

Convenience limits the length of portable ladders to approximately 30 ft. Ten-foot ladders, constructed of northern spruce side rails (or wood of similar strength) will be found satisfactory if of 1⅜ in. by 2⅜ in. material; 18 ft., 1⅜ in. by 2¾ in.; 25 ft., 1⅝ in. by 3 in.; 30 ft., 1⅞ in. by 3½ in. Rungs of 24 in. length seasoned ash should be 1⅛ in. diameter, with tenon of ⅞ in.; over 24 in. long, 1¼ in. diameter, with tenon of ⅞ in. Width at the bottom of most types of portable ladders should be appreciably greater than at top. Figs. 2 and 3 show good practice for fastening rungs to stringers. If the rung is inset in a binder strip and screwed to

the stringer with a wood screw through each rung, a safe and satisfactory construction will be reached.

Step-ladders should never exceed 20 ft.. in length, and have side rails from ⅞ in. by 3 in. to 1 in. by 4¼ in., the latter being used as the limit of length is approached. Steps vary from ¾ in. to 1 in. thick for the heavier types, and a slight increase in width is also recommended in very long ladders over the 4¼ in. of the shorter ladder. For every foot of length the bottom of a step-ladder should be 1½ in. wider than the top. Steps must afford a safe foothold, should be trussed, braced, or reinforced, and must be securely screwed or bolted to side rails.

Safe Practice

Use care in placing ladders. Do not place ladders too straight or at too great an angle, or they may fall, break, or slip. Never place ladders in front of doors opening towards the ladder. Ladders should never be placed against window sashes. Screw a board across the top of ladders to give bearing at each side of the window.

Step-ladders should be fully opened out in all cases before anyone steps on them. Always face ladder when ascending or descending. Do not go up or down a ladder without free use of both hands. If material has to be handled use a rope. Short ladders should not be spliced together, as they are not built strong enough to be used as long ladders.

Ladders should be kept clean and free from dirt or splashings of paint or material. Imperfections or defects are not readily observed unless ladders are kept in good condition. Iron and steel ladders should be coated with a preservative paint or composition. Wooden ladders, if used out of doors, should also be carefully treated with a suitable preservative, such as varnish or oil. Do not paint wooden ladders.

Safety belts and hooks should be provided when the character of the work demands the attention of the workman or constitutes an element of danger.

Stairways.

Ramps, used as a means of ascending or descending from one level to another if the grade is less than 20 deg. from the horizontal, should be rigid, with unobstructed passageway, bolted together. Cleats should be spaced about fourteen inches apart, and should extend from guard rail to guard rail, at right angles to the line of travel, except where a runway is necessary for wheelbarrows or trucks. Splinters, nails, patches, irregularities, breaks, or cracks in walking surfaces are dangerous, and should not be tolerated.

Ramps with granolithic or cement walking surfaces should have walking surfaces made anti-slip by rough floating, or by incorporating 1½ lb. per sq. ft. of abrasive grit, such as alundum in the mix for finish coat, and then sprinkling another 1½ lb. per sq. ft. over the surface before giving the rough float. Others prefer the use of in.-wide strips of anti-slip tread set 10 in. on centres in the cement at right angles to the line of travel and projecting less than ⅛ in. above the surface.

If the grade is greater than 20 deg. and less than 50 deg. from the horizontal, stairs should be used. Fixed ladders are necessary for grades over 50 deg.

For long stairways, landings between floors are desirable, dividing into approximately 12 ft. sections. Avoid doors opening on stairs, and provide landings sufficiently large to afford safe standing room outside of the space required by swing of door. Glass panels in doors opening on landings are necessary for safety, especially when swinging doors are used.

Treads

Stair treads and landings should be of sufficient strength to bear the maximum number of people that can stand upon them. Building codes generally require that the stair shall safely carry a load of 100 lb. per sq. ft. at the usual safe working stresses.

Width of treads and height of rise should be uniform for each flight of stairs, the tread giving ample width on which to place the full length of the foot when descending without danger of striking the heel against the riser above, but not so wide as to compel an increased stride. It is good practice to make the tread width (exclusive of nosing overhang), plus twice the riser height, equal to 25 in. In using this rule the thickness of the tread should be added to the height of the riser. The tread width should be further increased with a nosing overhang of ⅞ in. to 1¼ in., with the under edge rounded or bevelled.

Iron or steel treads are unsafe, as slipping is possible at all times. Under ordinary conditions marble, slate, wood, and other materials are safe, but mud, oil, or wear may render them unsafe. The safe type retains an effective and anti-slip quality for long periods even under exceptionally severe traffic. To this class belong cork, asphalt mastics, iron-abrasive, and lead-abrasive types of anti-slip treads. Concrete treads are sometimes used with anti-slip tread inserts to protect nosing from chipping, to prevent people from slipping, and take all the wear on an easily replaceable insert. Sometimes they are roughened by floating abrasive crystals into the setting concrete.

Height of the rise in conjunction with the width of tread determines the angle of the stairs, which should be between 30 deg and 36 deg. from the horizontal.

When the stringers of stairs do not accomplish the purpose, toe-boards should be added to fit snugly to the sides of treads and risers, and extend not less than 3 in. above the nosings. When stairways or runways are used for transporting materials a wire mesh guard should be filled in from toe-board to handrail.

Stairways 3½ ft. or more in width should have a handrail on each side. Open stairways, regardless of width, should have handrails on both sides, and stairways over 7 ft. in width should have handrails on both sides and in the centre. Measured from the centre of the tread the handrail should be about 42 in. high, because the average adult accidentally falling against the railing will strike with his weight under rather than above the rail. If the rail is properly braced, it will take up the force of the impact, and the intermediate rail will prevent the workman falling outside of the stair or runway. A young person would be saved from falling by the intermediate rail, which should be provided about midway between the toe-board and the upper or handrail.

Steel or iron angle or pipe is the best material if the railings will be subjected to strain, though wooden rails, if straight-grained and free from knots, imperfections, and splinters, are sometimes used when the traffic is light.

Rails made from angle iron or steel should have chamfered edges, an even, smooth surface, and the ends rounded or flush with upright. Supporting posts should be finished in a similar manner. 1¼ in. to 1½ in. pipe, with malleable fittings counterbored sufficiently to extend at least ¼ in. beyond threads on pipe, or 2 in. by 2¼ in. angle-steel for top rails and ¼ in. by 2 in. flat for intermediate rail; or 2 in. by 4 in. wooden top rail and 1 in. by 6 in. intermediate rail, will provide safe conditions. When metal handrails are used, supporting posts or braces should be spaced not more than 12 ft. apart. The railing will be stronger and safer if riveted instead of bolted together. In wooden construction it will be found advisable to space posts not more than 8 ft. from centre to centre to ensure rigidity. Supporting posts and braces should be of the same or larger dimensions than the railings. Handrails of enclosed stairways should extend about 3 in. from the wall to provide space for the hand to grip the railing and avoid scraping the fingers on the wall.

Circular stairways should be avoided in new construction. Existing circular stairways with narrow treads should be closed to all except employees whose work makes it necessary to use them. When circular stairways are necessary, variation in the width of tread should be avoided as far as possible, and effective and durable anti-slip should be used. Warning signs should be displayed at both top and bottom of such stairways.

Arrangement

Stairways located in dark places should have ample artificial light provided, so shaded as to throw the light on the stair and not in the eyes of the users. Especially good light should be provided at the commencement of each flight, at landings and platforms, so that the first tread and riser are clearly visible, as they are more important than the intermediate steps. Sufficient head room should be obtained, the ver-

Very High Pressures in Modern Practice

Central Station Plant of Public Service Company Uses a Boiler Pressure of 400 Lbs. Per Square Inch, Marking a New Advance in Engineering Practice on the American Continent

DURING the last few years there has been a distinct tendency in central-station engineering toward increasing the operating steam pressures. As a notable example of this tendency may be cited the new power station of the Public Service Company of northern Illinois, now being erected at Waukegan, about 40 miles north of Chicago.

The Waukegan station has been designed by Sargent & Lundy, Inc., engineers, and the steam pressure will be 400 lb. at the boilers—350 lb. to 375 lb. at the turbines. There are a few small experimental or test plants running intermittently at such pressures, but this will be the first central station in this country to employ a boiler pressure in excess of 350 lb., and the boiler that will be used embodies a radical departure in the matter of boiler design. The boilers are being built by the Babcock & Wilcox Company. They are entirely different from any B. & W. boilers thus far used and represent a boiler that has been developed by the engineers of that company working in conjunction with the engineers of Sargent & Lundy over a period of two or three years, with a view to obtaining a boiler that will be suitable for considerably higher pressures.

Small Individual Elements Essential

It has been recognized that in the design and construction of boilers for pressures in excess of 350 lb. the volume of individual elements of the boiler-pressure parts must be smaller than were formerly used in order that the failure of any single element shall not result in serious destruction. Further, small individual elements make possible the use of metal thicknesses for pressure parts of the high-pressure boiler no greater than, if as great as, that of the larger elements ordinarily used in the construction of boilers designed for ordinary pressures, and the difficulties that migh arise from excessive thickness of metal exposed to heat and pressure are thus obviated.

The general features of design of the combined boiler, superheater and economizer unit as finally adopted for Waukegan are indicated by the accompanying illustration. The position of the superheater and the path of the gases are particularly novel.

These new Babcock & Wilcox boilers are of the inclined header design, thirty-four sections wide, the sections being double-deck and connected to 54-in. cross drums. The lower sections are made up of eight 3¼-in. tubes, the tubes being 15 ft. long. Each upper section is composed of seventeen groups, each of two 2-in. tubes of the same length. The 3¼-in. and the groups of 2-in. tubes are so arranged and spaced that there are access lanes between all tubes horizontally and in two directions diagonally. The tubes of the lower sections are exposed for their full length to the direct radiant heat of the furnace, this portion of the boiler being constructed without baffles.

On account of the high superheat required, and also to avoid superheater being of excessive size, it is installed between the 3¼-in. tubes and the 2-in. tubes and is composed of three rows of 2-in. superheater loops.

Provision is made for removal of superheater tubes by connecting two of each three upper and lower section headers by long nipples and the third of each three sections having upper and lower headers by nipples which are shorter.

The gases pass from the furnace over the lower sections, which, as stated, are without baffles; thence over the superheater and into the upper deck, which is equipped with a single baffle, making this portion of the boiler two-pass. The gases are taken from the boiler through the long nipples connecting the upper and lower rear headers and are led to the top of an economizer at the rear of the boiler setting.

With the fuel to be burned and at the capacities that will be developed, there will be some tendency toward the formation of slag on the tubes of the lower section. Provision is made for the removal of such slag from the forward part of the lower tubes through special doors below the uptake headers, and at the rear through special doors opposite the nipples connecting the downtake headers to the mud drum, it being possible to use a "pokerod" between these nipples.

The superheater chamber is such that there is ample room for access above, below and between superheater loops and at the rear, below the second pass, to the superheater headers. This arrangement gives ample opportunity for periodical inspection and for thorough cleaning.

The economizer, placed at the rear of the boiler setting, is of the Babcock & Wilcox transverse-tube "Duratex" design and is built for a working pressure of 450 lb. It is thirty-six sections in height, each containing twenty 2-in. tubes, 20 ft. 10 in. long, connecting 7¼-in.-square wrought-steel economizer headers. Feed water enters the lower header at one side of the economizer and passes through a single row of tubes to the corresponding header on the other side. From this header the feed passes through a second row of tubes to a second header on the feed-inlet side of the economizer, and in a similar manner through all sections in series from the bottom to the top. This design with the downward passage of

gas and the upward passage of water through the economizer results in strict counterflow of water and gas which is essential for the best heat absorption, and the counterflow principle, together with the gas and water velocities employed, leads to maximum heat-transfer rates and corresponding maximum economizer efficiency.

Each boiler contains 14,086 sq. ft. of surface, the superheater 2,485 sq. ft. and the economizer 8,837 sq. ft. This boiler unit is designed for a normal output of 100,000 lb. to 120,000 lb. of steam per hour and a maximum of 150,000 lb., the steam to be superheated to 700 deg. Fahr.

Forced-Blast Chain Grates

The boilers, which are set with a 21-ft. 7 in. furnace height, are fired under the intake end and are equipped with Babcock & Wilcox forced-blast chain-grate stokers, each 21 ft. wide by 18 ft. 3 in. long, giving a grate surface of 383 sq. ft. and a ratio of grate to boiler-heating surface of approximately one to thirty-seven. The chain grates are equipped with side-wall and bridge-wall wrought-steel water boxes connected to the circulation of the boiler.

The engineers of the Babcock & Wilcox Company consider this design to be a great stride forward and think that it will be one of the most efficient boiler units yet developed, irrespective of pressure. Three of the complete Babcock & Wilcox units as described have been purchased for the Waukegan station, and three units of the same section, though not so wide, for the Grand Tower station of the Middle West Power Company, for which station Sargent & Lundy are also the engineers.

COAL ANALYSIS

The results of analyses of hundreds of coals from 25 states and the Territory of Alaska are given in Bulletin 193, "Analyses of mine and car samples of coal collected in the fiscal years 1916 to 1919," by Arno C. Fieldner, Walter A. Selvig, and J. W. Paul, just issued by the United States Bureau of Mines. Information as to the heating values of all coals tested is also given in the bulletin, which should be of interest to all extensive users of coal fuel.

Many mine samples of coal are analyzed each year in the laboratories of the Bureau of Mines. The analyses are made in connection with investigations relating to fuels belonging to or for the use of the United States Government, the causes of accidents in coal mines, the geologic relations of coal beds, and the quality and the value of the coal and lignite in the public lands. The systematic collection and analysis of such samples in connection with fuel investigations was begun in 1904 at the Government fuel-testing plant at the Louisiana Purchase Exposition, and was under the direction of the United States Geological Survey for six years. Descriptions of the coal samples collected between the beginning of this work, July 1, 1904, and the transfer of the fuel-testing and mine-accident investigations to the Bureau of Mines, July 1, 1910, were compiled and published in Bureau of Mines Bulletin 85. Descriptions and analyses of samples collected during the fiscal years 1913 to 1916 were published in Bureau of Mines Bulletin 123.

In order that the material in this bulletin may be used to supplement that presented in Bulletins 22, 85 and 123, the same plan of geological classification has been followed, the analyses and descriptions of the samples being grouped in alphabetical order according to States, county and town near which the mines or prospects sampled are situated.

Information regarding coal sampling and analytical methods employed by the Bureau of Mines and a bibliography on the coal resources of the world are contained in the bulletin.

The entire distribution of Bulletin 193 will be through the Superintendent of Documents, Government Printing Office, Washington, D. C., from whom the report may be obtained at a price of 35 cents. Bulletins 22, 85 and 123, the previously issued compilations of coal analyses made by the Bureau of Mines, are sold by the Superintendent of Documents at prices of 85, 45 and 50 cents, respectively.

POWER EXPOSITION AT NEW YORK

Engineers well known in industrial and public utility power generations make up the Advisory Committee which is guiding the National Exposition of Power and Mechanical Engineering. This exposition will open at the Grand Central Palace, New York City, on December 7th at noon and will extend through to December 13 (except the intervening Sunday). It will immediately follow the annual meetings of the American Society of Mechanical Engineers and the American Society of Refrigerating Engineers. Irving E. Moultrop, of Edison Electric Illuminating Co. of Boston, heads the Advisory Committee, and his colleagues are: Dexter S. Kimball, president of the American Society of Mechanical Engineers; Alexander G. Christie, chairman Power Division A.S.M.E.; Fred Felderman, national president National Association of Stationary Engineers; Milan R. Bump, president National Electric Light Association; N. A. Carle, vice president, Public Service Production Company of New Jersey; E. B. Katte, chief engineer, Electric Traction, N.Y.C. R.R. Co.; Fred R. Low, editor "Power"; David Mocat Myers, consulting engineer; Calvin W. Rice, secretary The American Society of Mechanical Engineers, and the managers, Charles F. Roth and Fred W. Payne.

This Advisory Committee is keenly alive to the importance of an exposition that will stress the engineering phases of the problems involved in the economical uses of fuel and the more effectual generation and utilization of power. The effect of such an exposition must be far-reaching and the plan outlined by the Committee insures a show that will benefit the manufacturer who uses only a small boiler for process steam as well as the engineers of the great cement, ceramics, metallurgical and power generation industries, whose fuel and power problems are extensive and severe.

The list of firms who have already reserved space shows that all apparatus and materials used in harnessing the energy released from fuels will be represented. The general appreciation of the importance of the exposition further insures the showing of the newest devices and best methods.

The program for the week has been arranged so that those interested especially in fuels and power can attend the technical sessions on these subjects at the annual meeting of the American Society of Mechanical Engineers. Sessions on Ash Handling Machinery, Stokers and Steam Utilization have already been announced; others are to come later and it is probable that the papers on these subjects will be amplified by the exhibits at the Exposition.

All members of the American Society of Mechanical Engineers who attend the meeting will receive the half fare return certificate which will enable them to attend the Exposition. Details of the certificate plan will be issued at a later date in the publications of the A.S.M.E.

The educational functions of such an exposition cannot be overemphasized. Not only is the contact between the purchaser and manufacturer of power plant equipment strengthened but there is the advantage of being able to compare displays and to choose that which is suitable and desirable.

LADDERS AND STAIRWAYS FOR POWER PLANTS

(Continued from page 22)

tical clearance being not less than 7 ft., measured from top of tread on a line with face of riser.

When the stairway ends in direct proximity to a crane runway, dangerous machinery, running belts, shafting, or traffic hazard, strong detour guard rails should be built and well braced to deflect traffic from the hazard. The floor at the head or foot of a stairway should be not less than 4 ft. from the nearest top or bottom riser.

No obstruction of any kind should be allowed in passageways leading to fire escapes, or on balconies, platforms, stairs, or landings of escapes. Each outside runway or stairway should have a cover or roof to keep off snow and ice, or if a cover is not provided, snow and ice should be immediately removed.

Combustion For the Boiler Room Operator

The Formation of Carbonic Acid, and Carbon Monoxide in the Furnace Gases is Discussed, and the Proper Proportion to be Aimed at, and the Reason, is Explained

By T. H. FENNER

IT WAS assumed in the last chapter that the fire had been started with clean grates, and had been built up to a proper operating thickness. We can further assume that the damper is set to create just the right amount of draught, and that we are getting the correct amount of air for proper combustion. In other words conditions are just about perfect. The process of combustion is the rapid combination of the carbon and hydro carbons of the fuel with the oxygen of the air, attended with the development of intense heat. Now we have seen that the air contains 21 parts of oxygen and 79 parts of nitrogen in every 100. When perfect combustion occurs, the carbon in the fuel and oxygen in the air unite in the proportion of one atom of carbon to two atoms of oxygen, forming a mixture which the chemist calls CO_2, or in ordinary language carbonic acid gas. Some of the hydrogen will combine with the oxygen in the coal to form water. A little explanation of these chemical changes will help the non-chemical reader to more readily grasp the idea. We have spoken earlier in these articles of the atomic weight of gases. Now just as specific gravity of any body is the ratio of its weight compared to the weight of an equal body of water, so is the atomic weight of any gas the ratio of the weight of its atoms compared to those of hydrogen gas. The specific gravity of water is 1. All other bodies will have a specific gravity of more than one or less than one. Hydrogen being the lightest known gas, its atomic weight is called 1, and the atomic weight of the other gases are multiples of one. The atomic weight of carbon is 12, while that of oxygen is 16. Thus in a molecule of water there will be a total atomic weight of 18, made up of two atoms of hydrogen, weighing each 1, and one atom of oxygen which having of weight of 16, makes a total of 18. The chemical formula is H_2O which means that there are two atoms of hydrogen and one atom of oxygen. In the same way CO_2 means there is one atom of carbon, and two atoms of oxygen, the atom of carbon of carbon having a weight of 12, and the two atoms of oxygen having a weight of 32, the total weight of the molecule being 44. If the carbon and oxygen combine in the ratio of one to one, forming CO, or carbon monoxide, the weight will be only 12 plus 16, or 28. We are not particularly interested in the matter of atomic weights, except so far as knowing just what we mean when we allude to CO_2, H_2O, and similar symbols.

When the oxygen in the air and the carbon unite in the ratio of one of carbon to two of oxygen, and form the mixture known as carbonic acid gas, or CO_2, the heat evolved by the chemical combination is 14,600 B. t. u. If insufficient air is supplied so that combustion is incomplete, and the carbon only combines with one atom of oxygen, the resulting combination, is carbon monoxide, or CO, and the heat evolved is only 4,400. We thus gather the idea that there must be two stages to combustion, a stage in which the combination is only partially performed, and a further stage in which the reaction is completed. The first stage is attended with only a small evolution of heat, and the second one with a much greater evolution. We can now trace these two stages in the fire which we have kindled in imagination.

We have then a bed of glowing coal, part of which is solid carbon, the lighter gases having been distilled off, and ignited by the heat of the refractory furnace lining. The air to support the combustion of this solid carbon must be passed through the fuel bed from the bottom up, as there is a greater pressure in the ashpit than there is over the fire in the furnace. We shall assume that in the condition prevailing in the furnace the fuel bed is of equal thickness throughout its length and breadth, and that the air will enter and pass through at all points with equal facility. The air in passing through the fuel bed, mixes intimately with it, and the carbon unites with the oxygen, each carbon particle being affiliated with two oxygen particles and the mixture of carbon, oxygen and nitrogen passes on through the setting, giving up its heat to the heating surfaces of the boiler as it moves over them.

Composition of Flue Gas

Now we can see what will be the make up of the gases leaving the boiler, knowing that what entered was simply nitrogen and oxygen, in the proportion of 79 to 21. We know that in the passage through the fire a certain amount of the oxygen combined with the carbon, and formed CO_2, so that we should naturally expect to find on analysis, that we had CO_2, nitrogen and oxygen. That is all right, but what proportion of each should we have? Now we are getting right down to the question of flue gas analysis.

Remember that in the case we are using for illustration, we have assumed a very clean even fire, and a supply of air thoroughly mixed with the fuel and should expect to get very good results. We shall then assume that the gases being analyzed, showed a percentage of 14 CO_2, and we congratulated ourselves on the fact. We did not bother to find out what proportion of the remaining 86% was oxygen or nitrogen, or whatever else it was, but were contented with the knowledge that the carbonic acid gas in the flue gases was equal to 14% of the total.

Now there is a peculiar property about the mixture of oxygen and carbon to form carbonic acid gas. It is that although there has been a combination of two different elements to form a new gas, the volume of the new gas is just the same as the volume of the original oxygen. That is, if we have 100 cubic feet of air, which is 21 c. f. oxygen and 79 c. f. nitrogen, and we pass this through the furnace, obtaining perfect combustion, this is what would take place. There would be just enough oxygen present to combine with the carbon, so that out of the 100 cubic feet, 21 cubic feet of oxygen would be changed into 21 cubic feet of CO_2, and the balance would be nitrogen. We must qualify this further, and say that if the fire was composed of pure carbon, and perfect combustion took place, with just the right amount of air, the resulting gases would be composed of 21 per cent. CO_2, and 79 per cent. nitrogen.

This then shows us that there is a definite ideal at which to aim, namely, 21% CO_2, but we have expressed ourselves as being well satisfied with the result of 14%. This is surely a great difference between theory and practice. Well, at first sight it looks that way, but we shall see that the difference is easily accounted for.

In the first place, the fuel in our furnace will not consist of pure carbon, and in the second place it is an utter impossibility to use exactly the right amount of air to ensure perfect combustion. We have to use more than enough in order to ensure getting quite enough. Thus we have two conditions which immediately destroy the ideal.

When we were discussing the quantity of air required to burn one pound of coal, we found that it was about 11.5 lbs. theoretically. In order to get the thorough mixture that is necessary we should have to use from 18 to 23 lbs. in actual practice. What effect will that have on the products of com-

bustion? Well, although there is just the same amount of carbon present to combine with oxygen, there will be double the amount of air present to supply that oxygen. It is obvious then that the percentage of CO_2 in the flue gases will be lower when we use a larger quantity of air than when we use just the required amount. To show the result in figures, suppose that instead of 100 cubic feet of air that we mentioned previously we now have 200 cubic feet, but the same quantity of fuel. The gases leaving the furnace then will be 21 parts of CO_2, but there will be 179 parts of nitrogen and oxygen not in combination. That is there are 100 parts more air than there was formerly, and the percentage of CO_2 wil now be

$$\frac{21 \times 100}{179} = 11.7\%$$

instead of 21 per cent. as before. This is the explanation of why excess air gives low CO_2. The products of combustion, when there is large quanity of excess air present, are diluted and instead of a rich mixture of CO_2 and a comparatively small amount of nitrogen and other gases, there is a weak mixture of CO_2 and a large proportion of nitrogen and free oxygen. CO_2 then is a positive measure of excess air, and that is where the value of gas analysis becomes apparent. CO_2 itself is a good guide, but when measured in conjunction with the proportion of oxygen or CO in the gas, it becomes a perfect pointer out of conditions.

Why should this excess air be detrimental to boiler efficiency? Well, as already stated, every pound of air that enters the furnace has to be raised in temperature by the combustion of the fuel, and this heated gas then gives up its heat to the water in the boiler through the heating surfaces. Now if large quantities of air are passed through the furnace over and above the amount necessary for good combustion, it is obvious that with a given quantity of heat available, the temperature of the gases will be lower than if a smaller quantity were used. Then we have a large quantity of gas at lower temperature. Another effect is present, and that is, owing to the much larger volume of gas, it has to attain a much higher velocity in passing through the boiler setting, the result being that a large quantity of the heat is carried away before it has a chance to pass through the heating surfaces. Thus we see that low CO_2, caused by excess air, causes a lower temperature in the furnace, but at the same time is usually accompanied by a higher temperature in the chimney gases, showing a larger amount of heat carried off up the stack.

We must admit then that we cannot hope to get our ideal CO_2 because of the necessity of passing excess air through the furnace, but we should try and keep this excess air down as much as possible. Another thing that will prevent us from getting the theoretical possible CO_2 is the composition of the fuel itself. It is obvious that if the fuel consists of only 70 to 80 per cent. carbon, that the mixture of carbon and oxygen will be lower than 21 per cent. For instance, if the fuel contains a certain amount of hydrogen, this hydrogen will combine with the oxygen in the coal itself in the proportion of 1 part hydrogen to eight oxygen and form water. This will cause the percentage of the carbonic acid gas in the total gas to be less than if the fuel had been all carbon. Therefore, we can see that when we got 14 per cent. CO_2 we were doing very well, as a practical proposition. Suppose that instead of passing too much air through the furnace we had passed too little. We should then have found a low percentage of CO_2 in the flue gas analysis. We should have also have noted a low temperature in the furnace, just as when we had too much air, but we should most likely have found the temperature of the chimney gases low also. In the case of low CO_2 in conjunction with too much air we found a low furnace temperature, but high chimney gas temperature. When we get low CO_2 through insufficient air, we get low furnace temperature, but also low flue gas temperature.

It is evident that both too little and too much air will give us low CO_2 readings, but by giving due attention to the other phenomena accompanying the low reading, we can diagnose the cause fairly well. We may say that the greater number of cases of loss of fuel through low CO_2 is due to excess air, and not to lack of sufficient air. There are so many places where air can find its way into a setting, that there is but little chance of there being a shortage under ordinary conditions.

If a shortage of air does occur, it means that instead of the carbon burning into carbon dioxide and developing 14,600 B. t. u. per lb. the reaction is only to carbon monoxide, developing 4,400 B. t. u. per lb.

If we get too much air we shall have highly heated gases passing up the stack without benefit to the boiler, causing immense losses of coal. If we get too little air we shall have large quantities of unburnt coal passing up the stack, causing large losses of coal. Evidently this question of getting the right quantity of air is something worth looking into. There is no method of checking furnace conditions so good as a proper use of flue gas analysis in conjunction with proper checks on temperatures.

The progress of events when CO is formed instead of CO_2 is, first, the air passes up through the burning coal on the fuel bed, and CO_2 is formed. When the carbonic acid gas passes through the fire, and into the combustion chamber, it meets more unburned carbon and each molecule of CO_2 takes up another atom of carbon, thus making two atoms of carbon to two atoms of oxygen, or C and O in equal proportions, CO.

When too much air is admitted, perfect combustion may be taking place, but owing to the large masses of inert gas or nitrogen that have to be heated, a large heat loss ensues, as already explained.

It is possible with a hand gas analyser to obtain the percentages of carbon dioxide, carbon monoxide, and oxygen, in the flue gases, but as a general rule, in ordinary practice, if the proportion of carbon dioxide is right, the other gases can be neglected. It is obvious that if the carbon dioxide is low through insufficient air, then there will be a large proportion of CO present in the gases, while if the CO_2 is low through too much air, the proportion of CO will be slight, but oxygen will be high.

It is possible to get CO even when CO_2 is good, but as a rule it will be only in very small quantities, and it is difficult to avoid. If you are getting from 12 to 14 per cent. CO_2, there will be but little cause to worry over the possible presence of CO, and if you admit more air to counteract the CO, you are going to lower the temperature of the furnace, and also the proportion of carbon dioxide. The operating engineer will find it pays him to confine his attention to getting the maximum possible CO_2, and letting the rest take care of itself.

Hand Gas Analysers

For taking samples of gas from different boilers and different parts of the same boilers, the hand gas anaylser of the Orsat type is a convenient and inexpensive instrument.

It consists of a measuring burette, or glass chamber, with suitable graduations, and three smaller glass chambers or pipettes, with which communcation is made by means of a tube, having a branch to each pipette. Each of these branches has a pinch catch on it, so that the tube and branches are like a steam header with three branches, and a valve on each branch. The end of this main tube or header goes to the sampling pipe in the boiler setting, and there is a main valve to close off the tube after the sample is taken. The gas is drawn through into the measuring burette by means of an aspirator, usually just the ordinary bulb such as is used in a syringe, the air all being expelled out of the burette and tube, and the gas rushing in to fill the vacuum when the pressure on the bulb is released. As soon as the sample is drawn into the meauring burette, the communication with the boiler is shut off, and three branch valves have of course been shut off all the time. There is thus a sample of gas filling the measuring burette and the tube. At the bottom of the burette is a tube communicating with a bottle filled with water and open to the atmosphere. This bottle is elevated, and the water runs into the burette, compressing the gas, until the

water in the burette reaches the zero mark on the scale. The leveling bottle should then be at such a height that the level of the surface of the water in the bottle and the zero mark on the burette are at the same height. There is thus a definite quantity of gas at atmospheric pressure in the burette. The pinch cock on the branch leading to

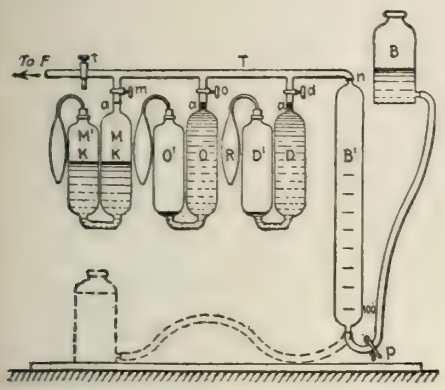

Diagram of Orsat Gas Apparatus.

the first vessel is now opened, and the filling bottle raised higher, so that the gas is forced into the first pipette. This contains a solution of caustic potash which possesses the property of absorbing CO_2. The gas is held in the pipette for a few seconds, and then the bottle is lowered, the water level in the burette as it falls drawing the sample of gas back from the first pipette. As soon as the water has reached the zero mark or a bit below it, the branch cock to the pipette is closed. The levelling bottle is then again raised, until the two levels are once more equal. Owing to some of the gas having been absorbed, there is less volume and the levels will be higher. The scale is graduated to read directly in percentages, and the more gas absorbed, the higher will be the level and the higher CO_2. If determinations of CO or O are required, the sample can be passed through the other two pipettes in order, in the same manner as the first one was. The absorbing material for the oxygen is a solution of potassium hydroxide, and pyrogallic acid. The absorbing medium for CO is cuprous chloride.

Care should be taken when first taking samples that all the air is removed from the tube and burette, and that the sample represents flue gases only.

The sampling pipe should be placed so that it is the centre of the last pass in a water tube boiler, and about the centre line of the tubes close to the head in a h. r. t. boiler. Perforated tubes are not recommended, an open ended pipe being better, care being taken that the opening is in the path of the gases.

All CO_2 recording machines are founded on the same principle as the Orsat, but being automatic, suitable mechanism is built into them to operate the pencil that marks the chart. The gas is usually drawn through the machine by a constant stream of water or a steam aspirator.

Temperatures

If conditions of combustion are good, we should have over the fire a temperature of about 2,000 degrees. This will decrease if the heating surfaces are in good order, and no leaks are present in the brickwork, to about 550 degrees in the base of the stack, or the blast pass as the case may be. The only way to get furnace temperatures is by means of a pyrometer, and this is not an ordinary instrument found in the boiler room. Flue gas temperatures are obtainable by means of a special thermometer of the portable type, or a recording thermometer such as manufactured by several makers. If the flue gases go much above 600 degrees, it is usually an evidence of too much air, unless the boiler is being worked at high ratings. High ratings involve intensive combustion, with very high temperatures, and the usual result is a much higher temperature in the flue gases, although the efficiency may be but little less than with the ordinary rating. It pays to lose a little efficiency owing to the saving in first cost and fixed charges, etc., by installing a smaller boiler plant, which can be forced up to 200 or 250 per cent. rating at certain periods of the day. The way to obtain good combustion is to watch carefully the brick work of the boiler, and see that all leaks are kept down. See that baffles are in good order and that there is no short

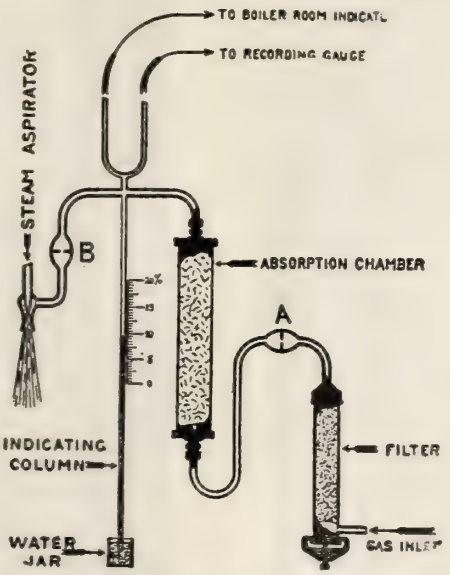

Diagram of CO2 Recorder and Indicator.

circuiting of gases between one pass and the next. Keep the fires the same thickness over the whole of the grate area, and avoid thin spots and holes. Regulate the damper when working with natural draught so that the air is sufficient but no more. Watch the flue gas temperatures, if you have the instruments to do so, and watch the CO_2 readings, and compare the two. If you have not got the instruments get the manager or owner to give you an hour of his time some day and explain carefully to him just what excess air or not enough air means to him in dollars and cents.

DETERMINATION OF HEATING VALUE OF COAL

The most accurate method of determining the total heating value of a coal sample is by combustion in a bomb calorimeter, states the Bureau of Mines in Bulletin 193, just issued. The instrument should be carefully standardized by burning substances of known calorific value, such as the standard samples of cane sugar, napthalene, and benzoic acid, that are now being furnished by the Bureau of Standards. The standardization should be conducted under exactly the same conditions and with the same thermometer that is used in the tests. The use of calibrated thermometers is essential. In carefully conducted calorimetric work the probable error should not exceed 0.2 per cent., which corresponds to about 30 B. t. u. in a high-grade coal. This degree of accuracy is higher than can be obtained in the usual methods of sampling, the error introduced by which oftentimes increases the total error to 100 B. t. u.

DETERMINATION OF GAS IN BOILER FEED WATER

Work is being done at Pittsburgh Pa., by the United States Bureau of Mines, on a portable method for determining the dissolved gases in boiler feed water, especially hydrogen. Some boiler feed waters have been found to contain more than 30 per cent. hydrogen.

EXPLOSIBILITY OF POWDERED COAL

The causes and effects of fires or explosions, due to the ignition of coal dust from the use of pulverized coal as a fuel, at a number of industrial plants, have been investigated by L. D. Tracy, coal mining engineer, of the Bureau of Mines. A bulletin on the general subject of coal dust explosion hazards in industrial plants will be issued by the Bureau at a later date.

BOOKLETS

Bearings and Bearing Metals is the title of an engineering bulletin just issued by the A. W. Cadman Manufacturing Co., Pittsburg, Pa. It contains a brief history of the development of bearing metals, covering the different types of metals and alloys used, the requirements of a bearing material, the friction in bearings and the proper lubrication of the same. This firm has likewise just issued a bulletin on Cadman metals which comprises a digest of sixty years' pioneer work in the development of fine bearing metals. Both of these booklets are short treatises of semi-technical information on bearing metals and their uses.

Application of Electric Steam Generators

The Development of the Water Resistance Type, Means of Regulating Supply of Water, and Methods Adopted to Safeguard the Apparatus, is Described in Detail

By P. S. GREGORY*

THE subject dealt with in this paper is the commercial application of electric energy for the production of steam by means of the water resistance type of electric steam generator.

The production of steam by means of electric energy is not a new process, and the water resistance type of electric steam generator has been in use in Europe for some fifteen years, though in the majority of installations in small sizes only, of 1,000 Kw. or less.

In general the cost of electric energy is such that it cannot be used commercially for the production of steam, but there are circumstances under which the conversion of electric energy into steam, even on a large scale, becomes economically feasible. The required conditions are a surplus amount of electric power, for which there is no other use at certain times, or a cheap supply of power. One or other of these conditions frequently exists in industrial plants. All manufacturers who purchase their power on a flat rate basis have at certain times in the day, or on certain days in the month, power available for which they have paid under their contract, but of which no use is made. The saving of coal which can be effected by the conversion of such surplus power into steam is a subject worthy of careful consideration. In the case of the existence of a cheap supply of power, the price which can be paid for this energy for the purpose of the production of steam is of course dependent upon the price of coal, and can readily be calculated.

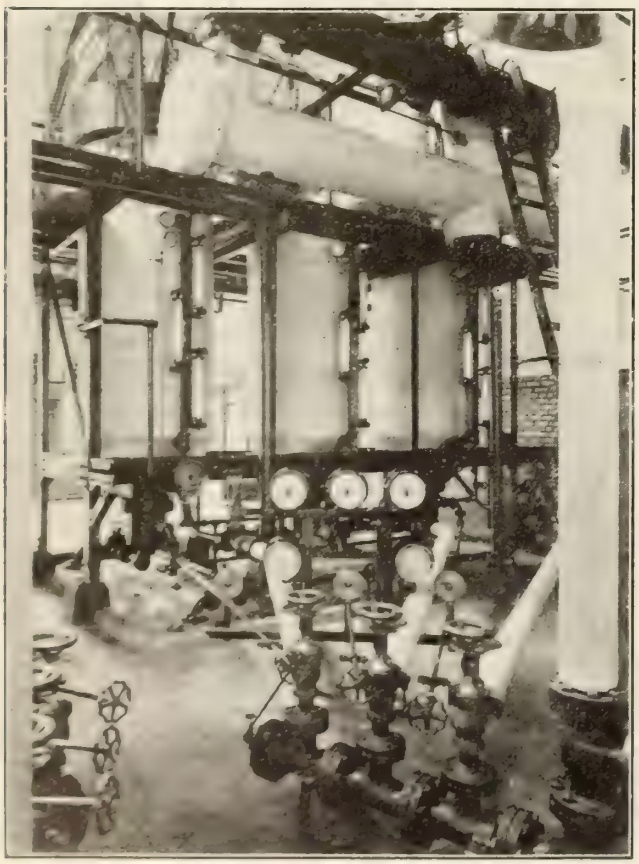
The fundamental relationship between electric energy and heat energy as pertaining to the production of steam may be stated as follows: One Kw. H. is equal to 3,412 British thermal units. In order to produce one pound of steam at a gauge pressure of 100 lb. per sq. inch, from feed water having an initial temperature of 150 deg. F., 1,070 B. t. u. are required. Therefore, if the conversion of electric energy into steam can be made at an efficiency of 97.5 per cent. one Kw. H. will produce 3.1 pounds of steam at the above conditions of temperature and pressure.

Under average conditions 1 pound of coal in a boiler will produce about 7.5 pounds of steam and therefore, the electric energy which is equivalent to one ton of coal is 15,000/3.1=4840 Kw. H. This is equivalent to approximately 200 Kw. for 24 hours, so that for each ton of coal per day to be replaced by electric energy, about 200 Kw. of electric steam generator capacity is necessary. On the basis of 4,840 Kw. H. being equivalent to one ton of coal, which is valued at say $8 under the boiler, the price which could be paid for electric energy would be 1.65 mils per Kw. H. If therefore, a supply of power is available at a price not greater than 165 mils per Kw. H. in a plant where coal costs $8 per ton or more, the production of steam by electric power is commercially feasible.

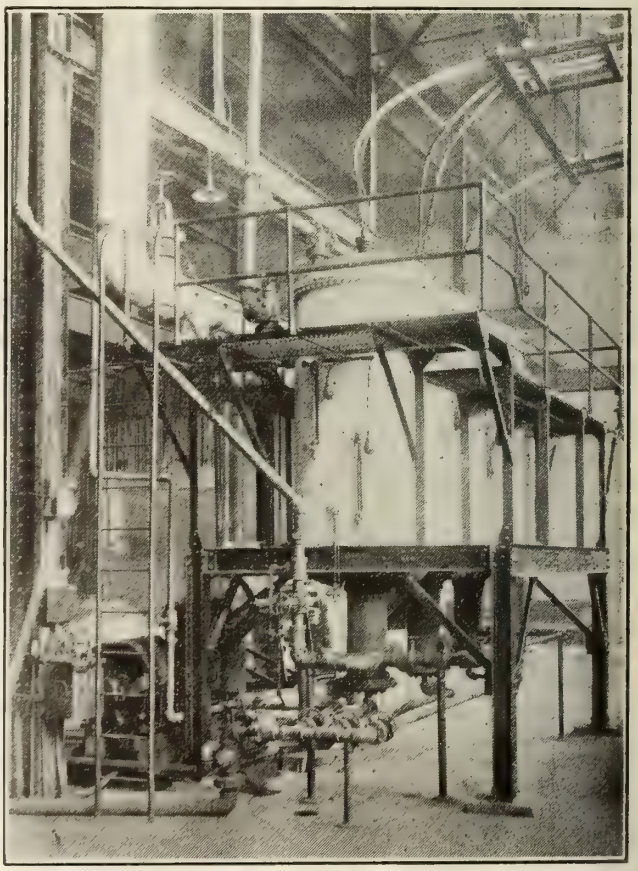
The water resistance electric steam

Paper read at meeting of American Electrochemical Society.

*The Shawinigan Water and Power Co.



An Electric Generator.



Another View of Generator.

generator consists essentially of a closed pressure vessel to which is connected a source of water supply, and from which water may be drawn off at the bottom and steam at the top. In this vessel electric energy is made to flow through the water from an electrode in the form of a plate, or tube, to the shell of the vessel, or to the metallic inner lining. Alternating current energy is used at a pressure varying from 110 up to 12,000 volts. The generators are constructed for the use of 3-phase power, either by employing three electrodes in one vessel, or by the use of three vessels with one electrode in each, in which case the outer shells are connected together in star. In this type of generator there is no heating surface, the generation of steam taking place throughout the water, and as a consequence no portion of the apparatus is at a higher temperature than the temperature of the steam. This is a most important feature from the viewpoint of safety and continuity of operation, as can be readily appreciated.

The chief advantages of the water resistance type of steam generator over the metallic resistance type are freedom from electrical and mechanical troubles, ease of regulation and cheapness. This type of generator has recently been further developed and made applicable to conditions on this continent by Mr. F. T. Kaelin, chief engineer of the Shawinigan Water and Power Co. Units of Mr. Kaelin's design, manufactured by the Dominion Engineering Works, Limited, Lachine, Que., and the Electric Furnace Construction Company, Philadelphia, Pa., are in operation up to 25,000 Kw. capacity. A full description of this type of generator is given in Mr. Kaelin's paper, read before the Montreal section of the Society of Chemical Industry, the Engineering Institute of Canada and the Canadian Institute of Mining and Metallurgy, on January 19, 1922. A low voltage type of water resistance generator was described at the fortieth general meeting of the American Electrochemical Society in October, 1921, by Messrs. Lidbury and Stamps.[3]

In the operation of this type of generator the load or electrical imput is dependent directly upon the area of electrode immersed in water, and inversely upon the resistance of the water. The variation of the water level or the area of immersion is affected by the operation of the valve in the feed water supply line. The resistance of water decreases with temperature, the relation being expressed by the formula[4]

$$R = \frac{C}{\sqrt{T^4}}$$

in which R = ohms per cubic inch, T is the temperature in °C, and C is a constant having a value of about 42,000 for raw river water, and about 87,000 for condensate containing 25 per cent. of make-up water.

The variation of the resistance of the water is effected by controlling the amount of water bled from the bottom of the generator. This water contains a comparatively high percentage of salts, and is therefore of a low resistance, so that an increase in the amount of water bled from the generator means an increase in the resistance of the remaining water and consequently a decrease in the load.

In actual operation it has been found that for ordinary fluctuations of load, such as are obtained in paper mills, a practical method of operation is to maintain a constant water level, and to vary the output of the generator by varying the resistance of the water by means of a bleeder valve.

There are in operation in Canada and in the United States at the present time installations of electric steam generators totalling about 150,000 Kw., which are for the most part installed in paper plants. One of these units is shown in the illustrations on page 28.

The accompanying diagrams illustrate the present development of the electric steam generator.

Fig. 1 shows a cross section of one of the three tanks of a 25,000 Kw., 6,600-volt unit. The electrode is supported at three points to give mechanical stiffness. The feed water is deflected around the sides of the tank by the funnel shaped casting shown in the bottom of the tank. It is found in operation that this method improves the cir-

culation of water in the generator, and consequently lessens the tendency to prime. The inner shells are separated from the main walls of the vessel, so that even in the event of an electric arc being established between the electrodes and this inner shell, and damaging the inner shell, no weakening of the outer wall would occur.

Fig. 2 illustrates a super-heater by means of which about 50° of the superheat may be given to the steam. The principle of the super-heater is as follows: Steam is generated at a pressure of 300 lb. and is fed into the super-heater, flowing outside of the super-heater tubes. It is then passed through a reducing valve, which reduces it to 150 lb. pressure, and it is fed into the superheater again, passing inside the superheater tubes and thence to the main steam line. The steam at 150 lb. pressure inside the tubes, being at 366° F., absorbs heat from the 300 lb. pressure steam outside the tubes, which is at a temperature of 420° F., and passes to the main steam line in a super-heated condition. The condensate from the super-heater is drained back into the boiler feed. In a super-heater designed to super-heat 20,000 lb. of steam per hour at 150 lb. pressure from 2 per cent. moisture at 50° of super-heat the total heat to be transferred was 616,000 B. t.u. per hour. The mean temperature difference was 30° F, and the heat transferred per square foot of heating surface per degree temperature difference was 68.5 B.t.u. per hour. The electrical energy required at 90 per cent. efficiency was 180 Kw. The advantage of this type of super-heater is that the amount of super-heat produced is constant, and that there is no overheating of the super-heater in case only a small amount of steam is being drawn from the generator.

Fig. 3 illustrates a generator fitted with a pressure regulating system of control, so that the operation is automatic and no attendant is required. The principle of operation is as follows:

Under normal running conditions the pressure regulator valve on the feed line, which is actuated by the pressure in the generator, is open. If the steam consumption is reduced so that the steam supply exceeds the demand, the pressure will rise, and owing to the operation of the pressure regulator valve in the feed control, the amount of water fed to the generator will be reduced, and the water level in the generator will gradually sink. This may continue until a water level is reached at which the float valve opens in the bleeder line, allowing a quantity of impure high conductivity water to be drawn off from the bottom of the tank. This will have the effect of increasing the resistance of the remaining water as well as still further reducing the water level and therefore of cutting down the flow of current until the supply of steam becomes only equal to the demand, and the pressure regulator valve is operated by the reduction in pressure and opens allowing more water to flow into the generator, gradually raising the water level.

The float valve in the bleeder line is closed by the rising water level, which after one or more cycles of operation will finally attain a position such that, for the particular conductivity of the water in the generator, will produce a steam supply equal to the demand.

If, on the other hand, the demand for steam exceeds the supply, the pressure in the generator will drop, and the pressure regulator valve in the feed line will therefore be opened wide and allow more water to flow into the gen-

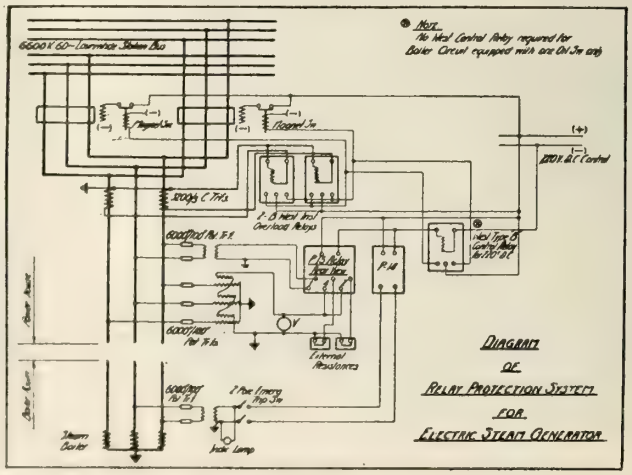

Fig. 4.

erator, raising the water level, and consequently increasing the steam supply until the pressure rises sufficiently to close slightly the pressure regulating valve, adjusting the inflow of water to the outflow of steam.

The possibility of the water level rising too high in the generator is avoided by the high level float valve in the feed line, which shuts off the water supply when the water level reaches the top of the electrodes.

A generator fitted with this system of automatic control, has been designed to supply low pressure steam for the heating of buildings. As the heating system is a closed system, the condensation being returned to the generator, it was not necessary to install a bleeder control valve on the heating generator.

The development of electric relay systems for the control of steam generators has kept apace with the other developments.

In the operation of the water resistance steam generator, the ordinary bugbear of low water has no terrors, but should an electric arc become established between one of the electrodes and the wall of the vessel, a dangerous condition would at once arise. This possible source of trouble has been avoided in two ways—by the installation of an inner protective shell separated from the outer wall by an inch or more, and by the development of a potential balance relay system by means of which should a ground occur on any one of the phases, the main circuit breaker is immediately opened. The opening of the circuit breaker does not depend upon the load on the generator, but only upon the potential balance, and the relay will function equally well from no load to full load, which is a very important consideration.

The complete electric relay system installed in connection with one of the larger units is illustrated in Fig. 4. The relays consist of the ordinary overload relays, the potential balance ground protection relays and an emergency hand-operated relay trip.

In order to make possible the application of the electric steam generator under conditions where a fixed amount of power is purchased, which is not all utilized in manufacturing operations, a relay system has been developed which will govern a total amount of power taken by the consumer, and will insure that all power not otherwise required will be utilized in the electric generator. The relay system is illustrated in Fig. 5.

The principle of operation consists in cutting in or out the feed water supply to the generator by means of the overload relays, which are operated by the total power consumed. The relays are so arranged that once the feed water is cut out it will not be cut in again until the total demand has been reduced some 10 per cent. below the contract amount. The shape of load curve obtained with a generator controlled by this type of relay system is therefore saw-toothed, and the relays can be so designed that the amount of available energy which is unused is less than 5 per cent. of the total energy purchased.

In conclusion it must be pointed out that the water resistance type of electric steam generator has now been developed to such a point that there is on the market today an apparatus suitable for the conversion of surplus electric energy into steam under almost any given conditions. Furthermore, in cases where power is cheap, or where fuel is expensive, or in special industrial processes, the electric steam generator can economically replace the coal-fired boiler.

NATIONAL ASSOCIATION OF PRACTICAL REFRIGERATING ENGINEERS

The thirteenth annual convention and exhibition of the National Association of Practical Refrigerating Engineers is to be held at the Planters Hotel, St. Louis, Missouri, this coming November 1st, 2nd, 3rd and 4th.

The Association expects a registration of at least five hundred members of its various subordinate chapters located in all parts of the United States, so this presents an inducement and the opportunity for every refrigeration and ice-making plant owner to have his manager, engineer or someone else connected with the operation of his large or small plant, come in contact with others similarly occupied and interested.

In this way much can be learned of what is going on in other cities and knowledge obtained of new things and new methods that should be useful and valuable to employees and employers.

Through coming in contact with others, the knowledge of their experiences would be taken up, the circle of their acquaintances extended and friendships formed that would be enjoyable and of benefit.

It should be kept firmly in mind that the first object of the Association is to further the education and worth of its members in the art and practices of refrigeration engineering.

The principal means toward this end is the holding of sessions for the reading and discussion of appropriate papers and for craft fellowship.

Each member subscribes to the belief of community of interests of employer and employee, and the Association is never used for the furtherance of strikes or anything that will interfere with perfectly harmonious co-operation between them.

The Association at no time takes partisan issue with rival interests in the refrigeration and ice-making businesses, nor is it used for political or religious purposes.

Its meetings are devoted to the business of the Association, and at all times preference is given to topics relating to the instruction and education of its members.

COMBUSTIBILITY OF COKE

Further work on the combustibility of coke and relative re-activity with carbon dioxide is being conducted by the Southern experiment station of the United States Bureau of Mines, Birmingham-Tuscaloosa, Alabama, in co-operation with the Pittsburgh, Pa., station of the bureau. Two variable properties of coke, namely, its combustibility and rate of oxidation or "solution" in carbon dioxide, are believed to play an important part in its performance in the blast furnace. It has been stated that the ideal coke should come down to the tuyere zone without oxidation by the carbon dioxide in the stack gases (Gruner's idea working) and should there burn rapidly carbon monoxide. Laboratory scale tests for determining relative combustibility of cokes and their reactivity with carbon dioxide have been developed and a number of by-product and beehive cokes tested. The relation between these values and the physical properties of the coke has been studied. A comparison of laboratory scale test results and results of actual furnace practice is being made.

Keith Electric Refrigerator Co., Toronto, have been incorporated to manufacture refrigerators and refrigerating plants and appliances.

The annual meeting of the American Electro-Chemical Society was held in Montreal during the past week. Many interesting papers in connection with electric heating were read and discussed.

A chain drive installation, said to be the largest in any grain elevator in the world, was recently placed in the Northern Central Elevator at Baltimore. This drive was one of 7,000 h.p. and made by the Morse Chain Co. Similar drives of approximately the same h.p. are located in other elevators in Canada and the United States.

Regina, Sask.—Construction of two giant oil tanks is planned by Imperial Oil Co. on the 40 acre tract of land adjoining the Regina plant, which was recently purchased by that company. These containers will be the largest of their kind in Canada, if not on the continent. Each will have a capacity of over 90,000 barrels of oil.

By the use of electric steam generators in the Laurentide Paper Mills and the Belgo-Canadian Pulp and Paper Co.'s plant in the St. Maurice Valley, four hundred tons of coal are saved daily. Unlike other systems of generating steam, the off-peak hours can be utilized for this purpose.

High Pressure Steam

IN THIS issue there is a description of a new design of boiler, which will work at the high pressure of 400 lbs. per square inch. In addition to this high pressure the steam will be superheated to a temperature of 700 degrees Fahrenheit.

It speaks very highly for the development of the materials with which the engineer can work, that these high pressures and temperatures have become possible in a plant such as central station of a public utility. It requires very special qualities in the metal of valves and valve seats to sustain the action of such high temperature steam without deformation and excoriation, and a few years ago such pressures were beyond the realms of possibility. We remember some twenty years ago, a number of large cargo vessels were built, having quadruple expansion with five cylinders, and a working pressure of 250 lbs. per square inch, but the troubles encountered with leaky valves and burnt out packing etc., discouraged any further development at that time. It was the practice in the British navy in high powered vessels to carry 250 to 300 lbs. per square inch at the boiler, but this was reduced to 180 or 200 lbs. at the stop valve of the high pressure cylinder.

The advent of the turbine has, of course, given the incentive and made the use of high pressure and high temperature steam a practical possibility. The greater the range of temperature between the entering steam and the exhaust the greater the efficiency, and as the final temperature is definitely limited, it is by increasing the initial heat that economies may be effected. Hence the 400 lbs. pressure and a temperature of 700 degrees.

Fascination in Engineering

WE DOUBT if there is any other profession or calling which offers its devotees more in the way of interest than engineering in any of its many branches. It would seem as though there is scarcely a week passes, but something new is developed, or something old is vastly improved. It is but a short while ago that we knew in an academical sort of way, that electricity was being used on the Continent of Europe to generate steam. Then, almost before we had time to consider the possibilities, we find that it is in actual use right in our own country. The actual application of 400 lbs. per square inch in a central station has come about without any flourish of trumpets, but in a perfectly normal way of progress. Then just as we have got into the habit of thinking that the day of the steam reciprocating engine in large sizes has passed, we get the news of an engine of this type being built of no less than 25,000 horse power, for the hardest possible service that an engine can be put to. When driving a rolling mill, as this engine will be doing, the load jumps from a minimum to a maximum, and reverses its direction many times a minute. When one thinks of the enormous weights of the reciprocating masses in an engine of this size, it induces a wholesome respect for the engineer who designs such a machine.

Outside of the realm of steam, but still in the field of power, the internal combustion engine has steadily forged ahead, overcoming the numerous initial difficulties with which it was beset, until it occupies a well recognized place, in the available catalogue of power producers. An internal combustion engine has been produced which utilises the principles of compound expansion of the gases in two cylinders, just as the compound steam engine does. All over the world research engineers are studying and experimenting to evolve the commercially possible gas turbine, as yet without success, but with enough partial success to encourage them to continue in their endeavors.

To the man who takes the right sort of interest in his profession, and is anxious to keep abreast of modern developments, there can be but little chance of dullness. There is but little excuse in these days of cheap publications for any one, however limited their time and opportunities, for falling into a rut, the sides of which hide the rest of the world from the unfortunate occupant.

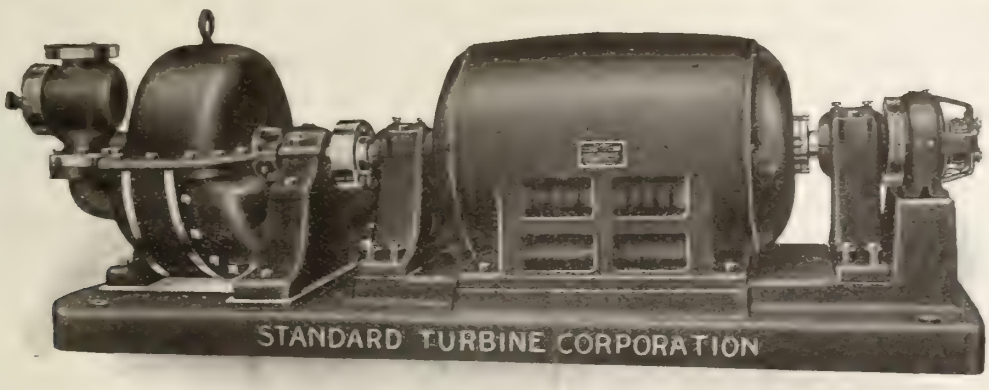
* * * *

Electric Steam Generating

SOME MONTHS ago we published an account of an electric steam generator, designed to make use of surplus power which would otherwise have been lost to the consumer. We are enabled again to publish further developments of this interesting apparatus, of a more detailed nature. To the engineer who has lived all his life in the shadow of danger from low water, there cannot help but be a certain appeal in a boiler that, as the water vanishes, simply gives up generating. No water, no heat is the rule in this apparatus. There is a danger, however, of a ground occurring between the shell of the boiler and the electrode when there is little or no water in the vessel, but this danger has been discounted by the introduction of a potential balance, which is independent of the load, but functions the moment any unbalancing of the phase potential such as would be caused by a ground occurs. The boiler has been made so as to automatically regulate its own pressure, by cutting the feed water in and out as the pressure rises or falls. This is made possible, of course, by the fact that the water itself supplies the resistance to the current, and therefore the amount of current flowing will depend on the amount of water present.

It has long been the dream of many hydro-electric enthusiasts to perform all power and heat development by means of electric power generated from water power. There are a good many obstacles in the way of those dreams being realized just yet, but the electric steam generator does certainly open a way, if fully utilized, of providing a steady twenty-four hour load, where there are at present short periods of high peaks, and long periods of little or no load.

Progress in New Equipment



Outside View of Turbo Generator.

A NEW MAKE OF STEAM TURBINES

The Standard Turbine Corporation of Wellsville, New York, are placing on the market a series of steam turbines in capacities up to 600 h.p. The following information has been given us by Mr. Willis D. Bishop, Montreal, who represents this company in Canada.

The various frames of turbines include one small size suitable for horse powers of 1-20th up to 10 h.p., for generator, pump and blower drive. The larger machines are built in single and multi-stage sizes for condensing and non-condensing service and are suitable for connecting to A.C. and D.C. generators, pumps, belt drives, fans and other types of mechanical applications.

The cut in Fig. 1 shows a small Standard turbine connected to a generator. This type of unit is built in capacities from 400 watts up to 15 kw. They are made for **use in hotels and apartment houses** to furnish light and power; the exhaust steam from the unit being used for heating and cooking purposes. In addition to its many other advantages this type of unit lends itself excellently to these purposes from the standpoint of cost of power even in cases where electrical power from a central station is available at low cost, for where it is possible to utilize the exhaust steam for the above mentioned purposes, the power becomes a by-product and the heat energy, not absorbed in the turbine, is available in the exhaust steam. The turbnie unit has fundamental advantages compared with engine driven machines in its quietness of operation, absence of vibration, and constant voltage irrespective of steam and load conditions, and also in the fact that it requires a minimum attention.

These machines are also used to good advantage for similar purposes in **laundries, small factories and mills.** The low steam consumption renders them entirely suitable even where the exhaust steam cannot be used. They are also used extensively in the **oil fields** around oil drilling and pumping rigs where they have proven advantageous because of their absolute safety and on account of convenience in handling due to their small size, light weight, and ease of installation and operation. The unit being completely enclosed having all moving parts in the interior thus being entirely weather-proof, it may be set up in any location and since two members of the machine are both together and on a common base plate, no special foundation is necessary for the machine, but a floor or wooden shelf is all that is required for its support.

These units may also be used to advantage in connection with **electric hoists** for generating current and electro magnets. They are then built in larger capacities of 7½ to 10 kw.

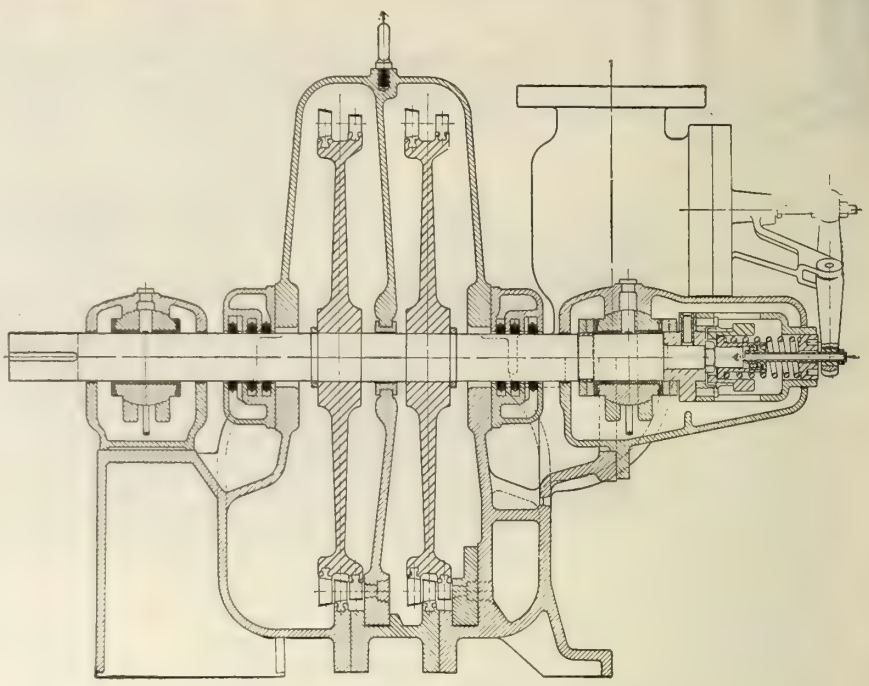
The turbines are all made for non-condensing service and will operate successfully under steam pressures down to 50 lb. per square inch. The casing of the turbine is made of close grain cast iron, tested hydraulically to twice the pressure which it will be subjected to in operation. The turbine rotor consists of a carbon steel wheel, bronze blades accurately milled to fit dove-tail in the wheel; the wheel being mounted on the shaft and the whole rotor carefully balanced. The nozzles are made of bronze to successfully withstand corrosive and erosive action as might otherwise take place due to the moisture in the steam generally found with boilers of the type used in oil fields, on electric cranes, etc. The governor is of the centrifugal type, all parts being carefully machined and balanced and of special patented design, having extreme simplicity and frictionless operation as its object. The governor has a total of five parts, mounted and attached securely to the rotor. The steam valve is of the balanced type and made of phosphor bronze so as to have the highest resistance against wire drawing action of the steam. The same turbines used for the above mentioned generator sets may also be used for other drives. They have in many instances been furnished for centrifugal pump drives, in refineries, milk plants, etc., and are also suitable for connection for fans and blowers, and centrifugals of various kinds. The sectional cut, Figure 2, illustrates a larger size of Standard steam turbine. These machines are built in single and multi-stage types for condensing and non-condensing service up to capacities of 600 h.p. The casing throughout is made of close grain cast iron or cast steel tested hydraulicly to a pressure twice that of the maximum working pressure. The steam end has bolted to it the nozzle ring in which are accurately reamed the first stage nozzles. The intermediate carries nearest the steam end the first row of stationary buckets and nearest the exhaust end it has inserted into it the diaphragm in which are reamed, or cast, the second stage nozzles. The exhaust end carries the second stationary row of buckets. On the horizontal joint of the lower half of the steam end there is a

flange for attachment of the turbine steam chest. This joint and the nozzle ring face are the only high pressure steam joints in the entire machine. The stem ring is stopped off at the horizontal joint so that there is no opening at this point through which leakage might otherwise occur to the interior of the turbine. The main bearings are either made of bronze or cast iron babbitt lined. The exhaust end bearing is supported on a pillow block resting upon a pedestal integral with the lower half of exhaust end thus having an especially rigid attachment to the base plate, thereby eliminating possibility for vibration and misalignment at the coupling end of the turbine which is of the greatest importance. The steam end bearing is directly under the bearing and the over-hang hence being short and rigid as compared with construction common on other turbines. The bearings proper are made in halves absolutely interchangeable and removable by the taking off of the caps. A thrust bearing is provided on the steam end, being made up by four collars attached to the shaft on threaded sleeves set into accurately machined grooves. These thrust collars are machined by special process whereby their faces will be perpendicular to the axis of the shaft. These thrust collars will permit of adjustment to the rotor in axial direction and will also permit of adjustment for wear on the bearing. Inherently the turbines have no end thrust but there are causes such as clogging up of blades with foreign material, etc., which may cause end thrust.

Shaft Packing

Leakage of steam at the casing ends is prevented by carbon rings set into packing cases. The packing rings have a liberal clearance on the sides so as not to become stuck between the partition walls, due to possible impurities in the steam and have a large clearance on their outside diameter to allow free movement in that direction and prevent possibility of their riding on the case. They however, have a small clearance by one to two thousandths of an inch on the shaft to prevent steam leakage at that point. The rings themselves are made in three segments, held together by a coil spring and prevented from rotating by means of stops set into milled slots in the cases.

The rotor consists of heavy steel shaft, upon which are mounted the bucket wheels, thrust collars, coupling and governor. The weight of the rotor and the shaft diameter are such that no critical speed will come any nearer an operating speed than 30 per cent. Disks which carry the rotating buckets are shrunk on to the shaft with a shrink fit heavy enough to overcome the maximum tensional stretch at the bore, and still have a liberal margin to insure good holding power on the shaft. The disks are made in one piece, each carrying two rows of buckets. This construction permits of a long fit on the shaft and also reduces the disk stresses at the hub materially. The wheels are made of high grade carbon steel thoroughly homogeneous and after machining are carefully balanced on specially prepared arbors. The wheels are keyed to the shaft securely. The revolving buckets are milled from bronze, cupro nickel, or monel metal, depending upon the steam conditions and are set into dove-tailed turned grooves in the wheel, spaced accurately relative to each other by means of accurately machined spacer pieces. Steam spillage on the outside is prevented by bands set into milled slots in the sides of the buckets and braced securely to these buckets. The construction of these shroud bands is such that they are prevented from being thrown off or damaged through the holding power of the buckets themselves. The bracing is not depended upon to prevent this. The bracing merely hinders the rings from sliding out sideways.



Sectional View of Turbine.

The Governor

The governor is of the centrifugal type and consists of two weights, fulcrumed on knife edges resting in hardened and ground knife edge seats in a governor housing attached by means of a housing hub to the shaft, the movement of the weights being resisted by a compression spring against a shaft sleeve, the outer end of the compression spring resting against an adjustable nut screwed into the housing. Adjustment of the speed is secured by the screwing down on the spring by means of this nut. The governor housing is made of best quality bronze, the weights are made of carbon steel and the sliding sleeve on the shaft is also made of steel. The governor housing hub, above mentioned, has a long fit on the turbine shaft to secure the most rigid and true attachment to the same and the joint between this hub and the housing is turned after the assembly of the hub on the shaft. This insures true running of the governor in all cases. Possibility of vibration in the outer end of the governor has been entirely forestalled in that the governor spindle has been made stationary and extending into the end of the shaft where the rotary motion is transferred into a lineal motion for the movement of the governor valve. The pivot block proper hence is directly at the end of the shaft and in the interior of the governor. This arrangement has another advantage not possessed to any degree by another type. It permits lubrication of the sliding shaft sleeve from the outside through the hollow governor spindle, which lubrication eliminates the wear on governor parts. Over travel of the weights is positively prevented by a heavy pin at the end of the shaft limiting the movement of the shaft sleeve. The governor housing is attached to the hub by means of four heavy bolts, two on each side of the knife edges. The governor is therefore entirely independent of the turbine shaft and may be removed from same without dismantling, and also can be tested independent of turbine shaft and attached to the same without disturbing the setting. The governor is quick in action in response to load or pressure changes, is stable, and requires a minimum attention.

An emergency governor is always provided which will automatically shut down the turbine should the speed exceed the normal speed by pre-determined amount, usually this amount is 10 per cent. The emergency governor consists of a plunger inserted into the governor hub, resisted by a spring of such characteristics that its initial com-

The Operators' Point of View

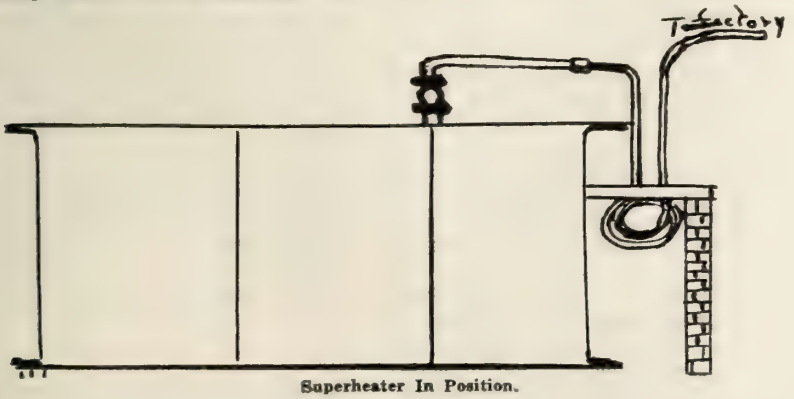
MAKING A SUPERHEATER

By A. E. Pritchard

In a candy factory where I used to work they had steam heated jacket copper kettles of various sizes for the purpose of cooking in the process of candy making. These kettles were

Coil Superheater.

bought second hand and with no stated pressure stamped on them to carry with safety, nor could the maker's name be found regarding them. However, we carried 125 lb. gauge on the boiler for some time when one day one kettle developed a large crack around near the bottom and steam leaked. Of course the operator closed the steam valve and fortunately there was no mishap. The boiler inspector was called to investigate the matter, and he said that we would have to reduce the pressure to 70 lbs., so we did. However, the candy makers found that this pressure was too slow, being not hot enough: 70 lbs. = 316° F.; 125 lbs. = 352.8° F., a difference of 32°, according to the steam tables for saturated steam. So to overcome the difficulty I installed a small superheater. The boiler was a 50 h.p. return tubular and the superheater consisted of a 1½-inch heavy steel pipe coiled into five coils; the steam after passing through the coil was superheated 60°. The change was very satisfactory and is still in operation over 5 years. The fuel was natural gas.



Superheater In Position.

KEEPING THE CO^2 RECORDER IN TRIM

By W. F. Schaphorst

Speak about a CO^2 recorder to the average steam engine operator and he is liable to take on a confused air because he doesn't know what CO^2 means, and feels that he is wading in beyond his depth in attempting to converse on such a subject. CO^2 belongs in the realm of chemistry and not in engineering according to the notions of the average engine runner.

However, there is nothing complex about operating a CO^2 testing machine. The engineer doesn't necessarily have to know anything about chemistry, even though combustion is a chemical process. He needn't even know what the chemical symbol CO^2 means. Continuous records are now made by a reliable machine that works automatically as long as it is in working trim. To keep in order is not a problem of chemistry, but one of mechanics, or perhaps some engineers would prefer to call it "engineering," in which case the engineer will fit into the job very well. Many engineers—thousands of them perhaps—are daily attending to their CO^2 machines and recorders and are doing their work perfectly. Yet they don't know any more about chemistry than any other average man who has never dabbled in chemistry.

If you have a CO^2 recorder in your plant you will find it a good plan to instruct several men in its care. There is no reason why the chief engineer alone should be able to care for it. In fact, it is better for the chief to assign the duty of keeping the analyzing machine a-going to a subordinate and make it his regular job. Should the chief attend to all such details himself he will certainly overlook them on days when he considers other work more important.

THAWING OUT PIPES

By J. Ellethorne

Winter will soon be with us and the problem of thawing frozen water pipes, many of them in locations difficult to get at, will have to be solved by the men in the power plant. Using the gasoline blow torch has its good and bad points, it is clean but the intense heat from the flame is liable to cause split pipes, due to rapid contraction or expansion. There is also the danger of firing the building when using it around dry and dusty places. Pouring hot water on a long length of pipe is a slow and unsatisfactory method for thawing a frozen water pipe. It usually gets the workman wet besides causing a nasty wet mess around before the job is finished. Whether using the flame or hot water method on a long line of pipe where the temperature is still low, some attempt should be made to secure an opening in the pipe so that the water from the ice will drain away as it is melted, otherwise it is liable to freeze up again before the entire length is thawed. The frozen pipe may be underground or in other locations where it is impossible to use either of the methods mentioned. Special electrical and steam apparatus is manufactured for thawing such pipes, but the average engineer can use a simple outfit of his own that will give very good service. A coil of ⅛ inch block tin pipe with an attachment on one end allowing it to be connected to a steam or hot water supply pipe is used. The frozen pipe is disconnected and the other end of the tin pipe is entered and the steam or hot water turned on. As the ice is melted the tin pipe is pushed in until all the ice is melted. This method is very successful in thawing service pipes as the line seldom contains elbows or bends. Of course a pipe so thawed will freeze again

in a short time unless the water in the pipe is kept moving, because the earth around the pipe is still frozen. If there are elbows in the line it may be necessary to dig down at the point where the elbow is located, this point can be determined by noting the length of tin pipe inserted. When high pressure steam of 50 pounds or more is available the elbow can be reached by attaching a steam hose to a five or six foot length of ¾ inch iron pipe with a handle attached so that it can be held in an upright position. This tool is used to thaw a hole in the earth. It will soon force a hole down to the elbow. It will also thaw the ground around the elbow, hence it will be unlikely to freeze again. Of course a valve must be used on the pipe so that the men using it can regulate the amount of steam. If there is no hurry to get at the frozen pipe underground and the exact location is known, it is possible to get it thawed by excavating a hole a couple of feet deep and filling it with unslacked lime, then pour some water on the lime and cover it over with boards and old rags or other cloth. The heat generated in the lime will thaw out the earth for several feet in depth in a few hours. If no tin pipe is available and the frozen pipe is fairly straight, small rubber tubing can be used but the hot water or steam may make it so soft that it can not be pushed ahead for long distances. The tin pipe is hard but pliable and can be pushed past long bends or double offsets without difficulty, often past 45 degree elbows but not through 90 degree ones.

BOILER INSPECTOR'S QUALIFICATIONS

By Jimmy Hamilton

There is a question that should be of interest to engineers, in the following. Have all Government and Insurance Company stationary steamboiler inspectors got engineer's certificates in Ontario? Should it not be compulsory as a matter of public safety that only men holding First Class papers be allowed to act in this capacity? The modern inspector is expected to certify, so long or so far as obtainable knowledge and practical experience permits, not only the safety of the boiler but also the condition of the safety and other valves, the condition and safety of the piping and other possibly dangerous equipment in the boiler room. His opinion and advice is often asked and acted upon in reference to engine room equipment, etc., so it appears to the onlooker that if a man in charge of a 600 B. H. P. plant is compelled to pass an examination for 1st class papers the man who certifies as to the public safety of the plant should also hold the high class papers. As a matter of fact, so far as I know, it is not compulsory for such an inspector to hold papers at all. Perhaps some such inspectors hold certificates for which they never passed a personal examination or perhaps only second or third class ones, nevertheless they give an O. K. certificate as to the safety of such large plants. Personally I believe a mistake was made in not having such an important item as part of the stationary engineers act. The ordinary man holding second or third class papers can do the ordinary inspecting, but the professional public inspectors should only be men holding First Class Papers.

HEAT LOSSES OF STORED COAL

Calorimeter tests to determine the losses in calories of coal heated in the air for various lengths of time are being made at the Pittsburgh, Pa., experiment station of the Bureau of Mines by J. F. Byrne. At 125° C. the following heat losses were obtained:

Time of heating	Per cent. loss
30 min.	.30
1 hour	.26
2 hours	.311
3 hours	1.01
20 hours	3.3
45 hours	5.7

Samples were heated for various periods of time ranging from ½ hour to 100 hours, and the b.t.u. run by the coal laboratory. The results show no regularly increasing loss in heating value as the time of heating increases. The coal samples show a change of weight on heating—at first a decrease in weight due to the loss of moisture. The decrease is generally less up to 24 hours, when there is an increase in weight of .64 per cent. After heating 100 hours at 125° C. there is an increase in weight of 1.35 per cent. and a loss in heating value of 3.02 per cent.

HIDDEN WEALTH IN COAL

Greater attention is being given today than ever before in the history of engineering to the subject of fuel economy. Scientist after scientist has pointed out that the world is wastefully consuming its coal resources; and on this and other grounds endeavors have been made to deal with coal more efficiently than by burning it under a boiler or converting it at a high temperature into gas with a hard coke and various tarry materials as by-products. Great hopes have been entertained of the process known as "low temperature carbonisation," which differs from the ordinary process in gas works by reason of the heating of the coal to a degree much below the usual standard. The object is to obtain not only a supply of gas but also a smokeless fuel which will burn brightly in the ordinary grate, and as many as possible of the various fuel oils and other products of value in one direction and another. The whole question, which is exceedingly complicated, has been investigated by a Fuel Research Board appointed by the British government. This Board, which has carried out experiments on a large scale, recently issued its report covering the work of the years 1920 and 1921. The problem is not yet solved, but the information which the Board has produced represents the highest point yet reached in the endeavor to find a sound commercial method of utilizing the manifold wealth hidden in our black diamonds.

ORIGIN OF NATURAL FUELS

In the course of the study of the origin and composition of coals, being made by Dr. Reinhardt Thiessen, associate chemist, at the Pittsburgh, Pa., experiment station of the Bureau of Mines, results have shown that the group o natural fuels that includes cannel coals, torbanite, certain kerosene shales, oil shales, and boghead coals can be divided into four classes according to origin. The origin of torbanite, coorongite, certain kerosene shales of Australia, the bogheads of Bathgate, Scotland, and other boghead coals has been established. The report of the investigation is being prepared.

NEW MAKE OF STEAM TURBINES

(Continued from page 34)

pression will hold the weight in place until tripping speed is reached at which point the rate of change in centrifugal force will exceed by a large amount the same rate of change in the compression force of the spring, the so-called scale of the spring being relatively low and the initial compression being fairly high. These characteristics will make the emergency trip pin come out suddenly and strike the trip lever a decided blow which will release the heavy relay spring closing a butterfly valve in the steam chest casing.

The governor valve is of the hollow poppett type carefully balanced to prevent undue forces on the governor mechanism due to static or dynamic pressure. The bronze seats are made integral with each other and with a bronze bushing set into the steam chest. This construction is superior to cast iron or steel bushings with set in seats as the expansion with this construction is the same as that of the valve. Thus the valve can be closed on both seats at the same time under all temperatures which is a condition difficult of fulfillment with any other construction. The fact that the seats may be removed is a decided advantage even though the materials used have the highest resistance against erosive action.

The trip valve is a butterfly valve entirely independent of the main valve which construction is to be preferred over having the main valve tripped by the emergency governor as no wire drawing can possibly erode the emergency governor valve to a point where it will not successfully shut off the valve when tripped. It is also to be preferred over a flapper valve which might have dirt and impurities lodged on the seat preventing the trip valve from closing off tight.

Babcock & Wilcox Chain Grate Stoker

For Natural Draft

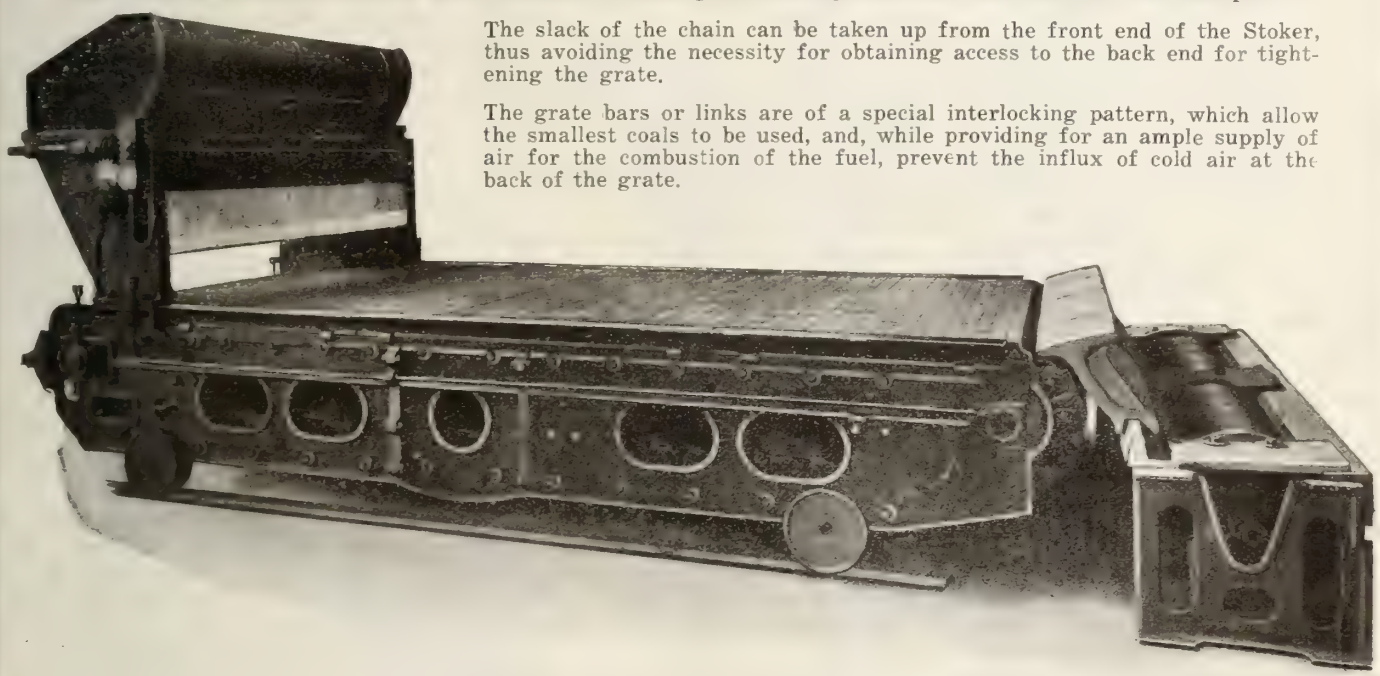
The grate consists of an endless chain of short interlocking cast-iron grate bars, linked together, running on angle irons and rollers and driven by a revolving shaft and sprocket wheels at the front end of the Stoker. The necessary power to drive the revolving drum is transmitted through a link chain and sprocket wheels from a shaft arranged either overhead or underground.

The starting or stopping of the Stoker, or the variation of speed, is effected through the B. & W. patent gear box, which can be driven at varying speeds. This box forms an oil bath in which the gear runs, and also contains an efficient clutch for putting the driving gear out of action should any unusual strain arise from an obstruction on the grate.

Any small repair, such as replacing a link, can be carried out with the Stoker in place under the boiler; but in case of need the whole Stoker can be brought out clear of the boiler, the frames being provided with wheels running on rails placed at the sides of the ashpit.

The slack of the chain can be taken up from the front end of the Stoker, thus avoiding the necessity for obtaining access to the back end for tightening the grate.

The grate bars or links are of a special interlocking pattern, which allow the smallest coals to be used, and, while providing for an ample supply of air for the combustion of the fuel, prevent the influx of cold air at the back of the grate.



The coal is fed over the whole width of the grate, and the depth of the fire is regulated by the adjustment of the vertically lifting fire door.

THE FEED OF THE COAL IS SLOW and the gas evolved from the fresh fuel as it drops on to the grate readily perfects its combustion by passing over the incandescent fuel further on.

The depth of the fire being regulated by a vertically lifting fire door, the Stoker CAN BE ADJUSTED IN A MOMENT to suit the class of fuel to be consumed and varying demands for steam, both by the depth of the fire and the speed of the grate.

The Stoker is easily manipulated and so simple that any fireman can understand it It is the only form of stoker in which the undue admission of air at the back of the grate is prevented and with it THE HIGHEST EFFICIENCY is obtained.

The Stoker ultimately proves itself the embodiment of economy because it is efficient and saves coal over any other method of firing and the cost of upkeep is low compared with any other type.

The first cost of some other makes may be less, but consideration must be given to whether they have the necessary metal in them to stand up under the work they are intended to do. By reducing the weight of metal the price can be lowered but only at the sacrifice of the durability, consequently the cost of repairs will be great. Due consideration should also be given to whether by any other method of firing the price of the Stoker can be recovered in the amount of coal saved in a given period.

WINDING OF DYNAMO

Question:—We have a D. C. Shunt-Motor 125 volts, 50 amps speed, 500 r. p. m., which we use for incandescent lighting. Would you kindly let me know through the Power House the No. of turns per pole and what size of wire it would require to compound this motor to make it suitable for a dynamo.

Answer:—In answer to your query we are again faced with the usual difficulty encountered on all electro-magnetic problems, viz: lack of knowledge concerning the permeability of the metal forming the poles of the electro-magnets. As this quantity varies between such wide limits, it is quite impossible (in the absence of such information) to do more than make a rough approximation.

The shunt wound generator in question is required to be changed into a compound wound generator.

Let us therefore make a "picture" of the characteristics of this machine, and just what it is proposed to achieve in the alteration.

(a) Shunt wound generator has a characteristic of the form shown in Fig. 1. The shunt circuit always being closed, the generator builds up a strong "field" and develops a high E. M. F. on open circuit.

When the external circuit is closed, the armature current increases, causing an increased armature resistance drop and reducing the P. D. This results in weakening the exciting current, which naturally results in a lowering of the E. M. F.

This decrease is steadily increased with increasing load; however within normal working limits this decrease in E. M. F. is not excessive.

(b) Series wound generator has a characteristic of the form shown in Fig. II. The exciting current is the same as the load current, in other words whatever value of current is being supplied, that value is flowing round the poles of the generator.

Seeing that the intensity of the magnetic field is dependent upon the number of ampere-turns round the electro-magnetics, we have a condition wherein the turns are a fixed number, but the amperes increase with the external demand for more current. Such increase will therefore automatically increase the number of ampere-turns, this in turn will increase the magnetic field, which in turn will increase the E. M. F. of the generator.

Hence the reason for the "rising characteristic" of the curve shown in Fig. II.

We now have two conditions under consideration.

(a) Shunt winding, with a "falling characteristic."

(b) Series winding with a "rising characteristic."

It will therefore be obvious that if we combine the two systems of winding the field coils, the "falling characteristic" will tend to neutralize the "rising characteristic" and vice versa.

Such a system of winding is known as compound winding, this in turn may be divided into two types:

(a) Flat compound.

(b) Over compound.

Flat compound is when the series winding just has a sufficient number of ampere turns to maintain the voltage of the machine constant at all loads.

Over compound is when the series winding has a few more ampere turns than are necessary to maintain a constant voltage at all loads, and so increases the voltage of the machine corresponding to an increase in load.

These compound windings may be arranged on the pole pieces in different ways.

(a) Series windings outside the shunt windings.

(b) Shunt windings outside the series windings.

(c) Series windings at one end of pole pieces.

If magnetic circuit through iron work is good, the position of the coils of the various types of windings makes little difference.

It is important, however, that a size of wire should be chosen for the series windings that will offer the minimum resistance.

In the case of the machine mentioned in this query, we shall have no alternative but to wind the compound winding over the shunt winding (which is already fixed).

This particular machine is already developing a magnetic field of the proportions of which we have no knowledge. Therefore it is impossible for us to determine the necessary amount of series ampere-turns to make this machine into a compound one.

This may be experimentally determined as follows:

Connect up the machine to its load as usual, but insert an ammeter in the shunt winding circuit, so we can learn the value of the amperes in the field coils.

Count the number of turns of wire on one of the pole pieces then when we learn from the ammeter in the shunt winding, the number of amperes flowing round the winding, we shall know the number of ampere-turns in the shunt winding.

The shunt turns will be constant, but the amperes flowing through these turns will vary with the load on the machine. We can therefore easily determine the percentage increase in the number of ampere-turns from no load to full load.

Therefore take the reading on ammeter in shunt winding, when the machine is running at correct speed, and developing its normal voltage, but operating under no load.

Then gradually connect a load until the machine is operating at full load.

WINDING OF DYNAMO

(Continued from page 38)

whilst generating its normal voltage.

The number of series turns necessary to convert the above into a compound machine, will then be represented by the following equation:
(A. T. at full load — A. T. at no load). Divided by full load current.

As the resultant series turns will be expressed in ampere-turns, it will be necessary to divide this by the full load current of the machine which in this case is 50 amps. to obtain the number of turns of wire required.

The size of wire is determined by the amount of current it has to carry without overheating, with resultant excessive drop of volts.

It is very sound practice to take as a standard a current density of 1,000 amps. per sq. inch. If, therefore, 1,000 amps. needs 1 sq. inch, then 50 amps. being only one twentieth part of a thousand, will only need a similar proportion of a sq. in. This will be .05 sq. in.

It should be borne in mind that a compound wound machine is not suitable for charging storage batteries, therefore, if such a thing is contemplated, it would be necessary to insert a single pole switch in the series winding circuit, to permit of the series winding being "cut out" whenever the machine was being utilized for the charging of storage batteries.

There are many factors which enter into such a problem as this, such as air gap, dispersion factor, shape of edges of pole pieces, reluctance and permeability of the iron, etc.

Even in the designing room considerable leeway is permitted in the compounding of dynamos, the final corrections being made whilst on the test bed, in the old-fashioned method of "trial and error."

The instructions contained in this article will result in a reasonable degree of accuracy being achieved.

Finally it is usual to provide from 3 to 5 per cent. over compounding for lighting loads, and as much as 10 per cent. over compounding for traction loads. The additional ampere turns will be represented by an increase by similar percentages, as the amount of over compounding required.

—Geo. R. Archdeacon A. M. I. E. E.

COMPRESSED AIR FOR PULVERIZED FUEL

Some further details regarding the equipment to be used in handling the pulverized coal at the New Cahokia Station of the Union Electric Light & Power Company, St. Louis, Mo., has been announced.

Among these the method of weighing the fuel and conveying it from the pulverizers to the boilers is of unusual interest.

Below the floor level of the pulverizing room will be placed a series of five blowing tanks, which serve an equal number of twin pulverizing units. These blowing tanks will rest on platform scales, the dial of which will indicate to the operator in the pulverizing room the amount of fuel in the tank.

The fuel will feed into these tanks by gravity as desired from pulverizing fuel bins in the pulverizing room. Each charge will be automatically weighed and then elevated by compressed air to a height of about 75 feet through 4-inch pipes. By means of a simple system of switching valves and parallel distributing mains, cross connected, any blowing unit can discharge into any of the eight enclosed storage hoppers in the boiler house. These hoppers serve the four pairs of boilers of 1780 h.p. each, comprising the first group of boiler units to be installed.

The fuel requirements for the first group of units are estimated at 1,000 tons in 16 hours.

The accompanying drawing shows the general arrangement of blowing tanks with relation to the boilers. This equipment was selected on account of its cleanliness and freedom from mechanical complications which would be liable to interrupt service. Contract has been awarded Quigley Fuel Systems, Inc., New York.

40 YEARS OF GROWTH IN ELECTRICITY

Things that have been happening recently remind us of the newness of the environment we live and work in. The death of Alexander Graham Bell brought to mind the fact that the telephone—the little instrument that jingles on the desk all day—was invented more than a generation ago. Then came a further reminder—the 40th anniversary of the establishment by Thomas A. Edison of the first electrical central station in the world.

Astounding changes have taken place in the past 40 years. A man of 40 has passed through only the preliminary stages of his life, and is just about to enter its most fruitful period; yet the electric light, the generator, the motor and most of the other commonplace industrial devices of to-day are no older than he.

Forty years ago the first electric light bulb, illuminated by a current which had been generated in a dynamo and carried through the street by a feeder wire, blazed up in a building in lower New York. The entire apparatus involved was totally new. When the idea of a central station to supply light to an entire district occurred to Mr. Edison he found it necessary, in order to carry the idea into effect, to invent not only the incandescent bulb, but the dynamos that generated the current and the system of feeders that carried it to the bulbs.

40 Years of Growth

The technique of applying electricity to industrial uses has developed so tremendously since that time that it is impracticable even to catalogue the improvements. Telegraphy was virtually the only important application of electricity that in 1882 had reached anything closely resembling its present form. Even that has undergone technical improvements in the past 40 years. Automatic receiving and sending devices have been perfected, relays have been devised to facilitate long-distance transmission of signals, systems of multiplex telegraphy have been invented that greatly reduce the cost of sending messages, and sensitive receiving machines have been constructed that make the operation of trans-oceanic cables efficient and accurate. The telephone, which was in a rudimentary stage when Edison opened his first central station, has been brought to a point of development which could not have been predicted in those days. The latest great development in this field is the automatic switchboard, which practically eliminates the need of "hello" girls. The New York Telephone Co., in co-operation with the Western Electric Co., is now engaged in the gigantic task of installing these machine switchboards which may serve the 1,044,000 subscribers of New York City on August 31, 1922.

The art of converting mechanical energy into electrical energy, transmitting it through wires, and reconverting it to mechanical power to drive machines, has taken enormous strides. The use of electrical power in industry was unknown then; electricity is now one of the chief methods of supplying industrial power, and the further development and application of this technique is one of

Sole Makers for Canada

20 McGee Street PHONE: G. 3660 Toronto, Ont.

WE GUARANTEE that with the use of CYCLONE SHAKING AND DUMPING GRATE any grade of hard or soft coal, **or screenings of same,** can be burned with excellent results both as regards Economy and Capacity; that the total annual expense to the user for coal, interest, depreciation, repairs, damage to boiler, liability of shut-down, etc., will be much less than would be the case with any other type of Grate or Stoker on the market.

40 YEARS OF GROWTH

(Continued from page 40)

the chief problems of our future industrial development. It is a long step from Edison's first central station to the super-power plant to supply the entire North American seaboard from one great transmission line; yet that is the stride which has been taken in 40 years.

How Far Will it Go?

The devices for the use of electricity in the home and the factory for other purposes than the production of power and light and the transmission of messages are myriad. The electric furnace—to mention only one of them—has made possible the attainment of unbelievable high temperatures. One other paramount development must be mentioned—radio.

The transmission of telegraphic signals and human speech through the ether is a source of perpetual wonder. The radio has been responsible for the mushroom growth of a branch of the electrical industry in the United States that has attracted as high as $5,000,000 of new capital in a single week.

The electrical industry which has grown up since 1882 enters into every part of our home and industrial life. It runs our machines, lights our homes, carries our messages, and amuses us. But it is still young. No one could have predicted 40 years ago how vast would be the application of electricity to-day; no one can predict the situation 40 years in the future. One thing only can be said with certainty—we have seen only the beginnings of electrical development. The use of electricity will grow, perhaps, to a more vast extent than we can now imagine.

—From The Industrial Digest.

A VALVELESS PUMP

Every user of a reciprocating pump knows the endless trouble which arises in connection with the valves. However carefully these are designed and however well they are manufactured, they sooner or later require replacing or repairing owing to the heavy strain which is placed on them. With these difficulties in view countless inventors have tried to make a reciprocating pump without valves; but complete success seems to have been reserved for a British engineer. His pump has no valves and is so constructed that its cylinders fill and discharge completely on every stroke thus giving the highest possible efficiency. The only parts liable to repair or replacement are those employed in the driving head, and they are all easily accessible and are standardized at slight cost. The materials used are specially selected to ensure the maximum of wear. During a test recently carried out on a six-inch pump driven by a one horse-power motor, 5,000 gallons of water were pumped per hour against a head of about six feet.

COAL BRIQUETTING MADE PERFECT

The advantages to be derived from compressing coal dust into solid blocks of fuel have been recognized for many years, and briquettes of this type are in use for a great variety of purposes. Hitherto they have all suffered from the drawback that a large amount of tarry binding material has been used in order to consolidate the dust; and this binding material gives a smoky flame and prevents the briquette from burning brightly. This drawback is completely overcome in a new briquetting system invented by a British company and recently tested with complete success. Ground-up coal is mixed with about half the quantity of water and placed in a special form of press which squeezes out practically all the water. The water, in fact, comes out as a clear jet, and the briquette itself is produced in a compact shape with a more or less hard surface. Within a few hours the briquette is so hard that it can be thrown about without breaking. The amount of binding material required is only about one third of that usually employed and its fuel value is consequently much superior. When burned this fuel opens out well in the fire and burns brightly. Experts declare that this invention marks a revolution in the briquetting industry. Both in capital cost and in working expenses the new system is cheaper than its rivals.

BOOK REVIEW

We have received from the D. Van Norstrand Co., New York, a copy of the third edition of "Mechanical Laboratory Methods" by Julian C. Smallwood, M.E. In this edition the work has been brought thoroughly up to date, and the Definitions and Values Code of the A.S.M.E. Power Test Committee has been included in the work. The book goes into methods of testing practically every mechanical device used in power plant work, and shows how these different instruments must be calibrated before commencing tests. The title is somewhat apt to make the operating engineer think the book is too much of a test engineer's book to suit him, but this is not the case. It should be of the greatest use to any operating engineer as well as to the man whose vocation is purely that of the efficiency engineer. The volume is published at $3.50 in the U. S.

De Laval Oil Purifiers

are protecting the turbines and transformers of the Queenston Station of the Ontario Hydro Power Commission. After centrifugal purification or dehydration, no sludge or moisture remains in the oil to lower its insulating efficiency.

The De Lavals effect a saving of oil, prolong the life of the turbine and decrease the cost of transformer maintenance.

Wherever the preservation of oil efficiency is demanded—regardless of the size of the plant—there should be a De Laval.

SCORED JOURNALS MADE SMOOTH

Magnolia Anti-Friction Metal is the one lining that completely fills in and smooths over scratches and irregularities in the journal surface. It has the peculiar property of imparting high polish alike to shaft and box surfaces and keeping the whole bearing cool and in prime condition.

Try a Magnolia lining on your next hot-box or "hopeless" case and you will quickly see why so many of our customers would use no other bearing metal even if others could be had for nothing.

Ask your dealer or write us direct.

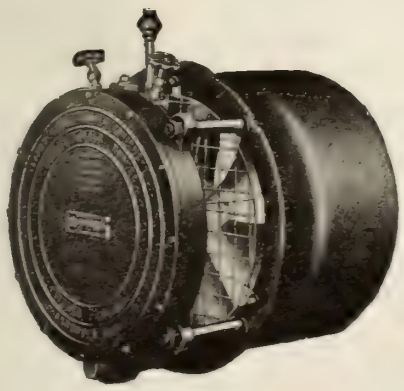
TURBO BLOWER



Solve the Coal Shortage Problem

YOU can adopt no more effective means to meet fuel shortage than by installing Coppus Turbo Blowers. They make it possible to burn low grade fuel with satisfactory results. Because of this and many other economies effected by their use many of Canada's largest plants have adopted Coppus equipment. To wit:

T. Eaton Co., Hamilton; **Farmers' Dairy Co.**, Toronto and Napanee; **Simpson Knitting Co.**, Toronto; **Canada Foundries & Forgings**, Welland and Brockville; **Can. National Rys.**, Leaside; **St. Michael's Hospital**, Toronto; **Municipal Abattoir**, Toronto; **Goodyear Tire & Rubber Co.**, Bowmanville; **Davis Leather Co.**, Newmarket, and several other firms.

Investigate Coppus Blowers now—full information promptly furnished.

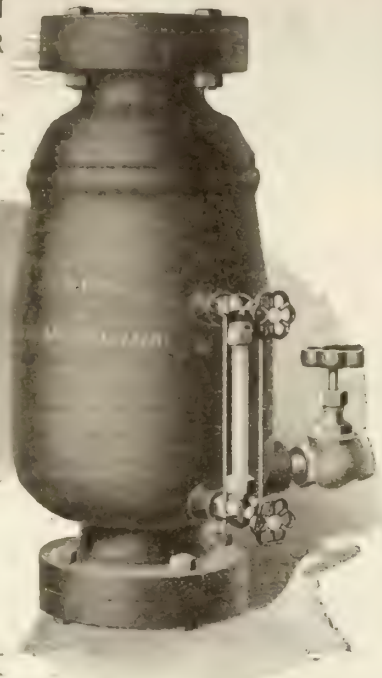
Insure Your Engines

THE ANDERSON STEAM SEPARATOR



[illegible] a positive insurance against engine breakdowns due to accumulated moisture in engine cylinders and turbine casings. It is an insurance against expensive idleness of both engine and men.

The Anderson delivers dry steam under all operating conditions.

The moisture is completely separated by the combined action of centrifugal force and the sudden reversal of high velocity steam current—and the moisture cannot be picked up again, when once separated.

You really need the Anderson—Let us tell you more about it.

Sounds an alarm

—when danger is near

LUNKENHEIMER

"Vigilant" Safety Water Column

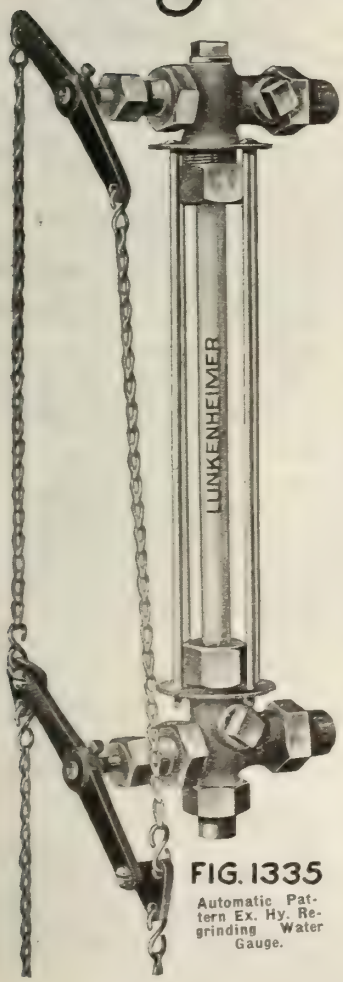

FIG. 1335

Automatic Pattern Ex. Hy. Regrinding Water Gauge.

A safety device as essential for the protection of the boiler against extreme high or low water levels as the Pop Safety Valve is against excessive steam pressure.

The Lunkenheimer "Vigilant" Safety Water Column sounds an alarm before the water reaches either danger limit. It thereby aids in protecting the boiler against accident and in safeguarding the boiler attendants against injury or death and the plant from destruction.

Statistics covering boiler accidents will prove the desirability—yes, necessity—of equipping boilers with the Lunkenheimer "Vigilant" Safety Water Column.

For working steam pressures up to 250 lbs., with a size to fit every boiler, and a variety of Water Gauges and Gauge Cocks available to meet individual requirements.

ASK FOR BOOKLET 519-DC.

Re-line--for the last time!

PUT furnace troubles behind you—do it the modern way, the easy way, the economical way—by relining with jointless, trouble-free

PLIBRICO JOINTLESS FURNACE LINING

Plibrico, the jointless fire brick, is the universal lining for furnaces of every size, new and old. This superior furnace lining is a plastic refractory that can be molded to conform to any furnace design by anyone who can use a mallet and trowel. When vitrified it forms a setting that is solid as rock, resistant to furnace temperatures up to 3,100 deg. F., and above all is jointless.

Send for our booklet on "Modern Furnace Building" and ask our nearest representative to call. PLIBRICO is delivered only in steel containers of distinctive appearance as shown at the right.

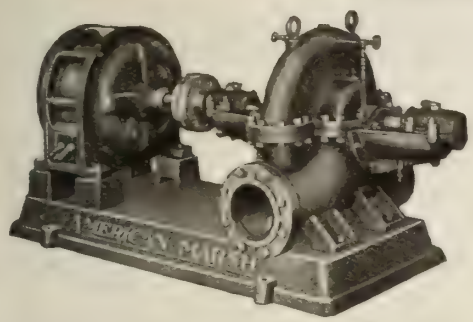
AMERICAN-MARSH PUMPS

Centrifugal and Direct Acting



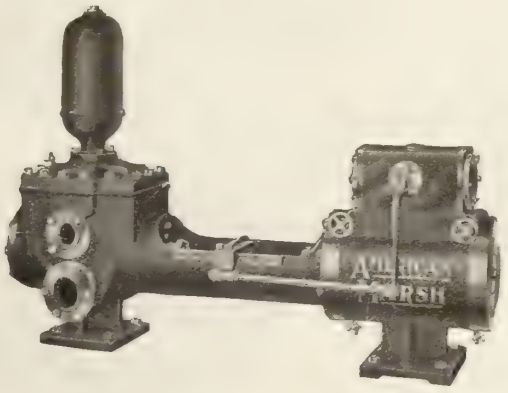
Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The Line includes :

Boiler Feed Pumps	Jet Condensers
Air Compressors	Vacuum Pumps
Deep Well Engines	Condensation Pumps
Centrifugal Pumps	Sump Pumps



May we send you our general Catalog ?

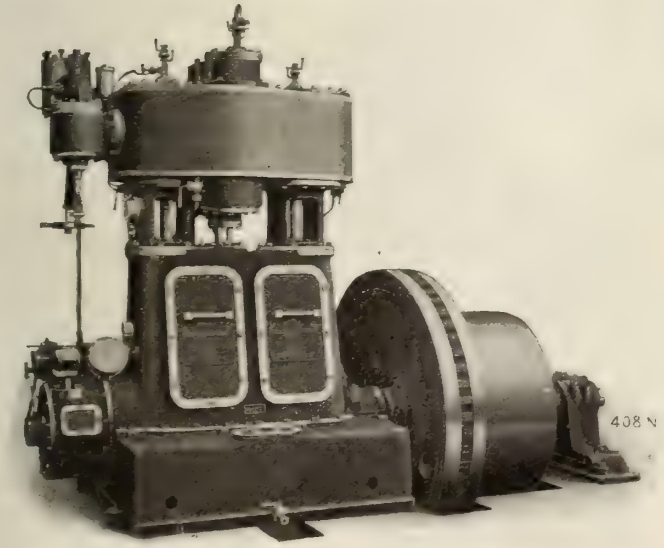
AMERICAN STEAM PUMP CO.

BATTLE CREEK, MICH.

CANADIAN AGENTS:—A. R. Williams Machinery Co., Ltd., Toronto; Williams & Wilson, Ltd., Montreal; London Engine Supplies Co., Ltd., London: A. R. Williams Machinery Co., Ltd., Winnipeg; Mechanics' Supply Co., Ltd., Quebec; Gorman's Ltd., Edmonton and Calgary; J. T. Allan Ritchie, Vancouver.

BELLISS & MORCOM LTD.

Birmingham, England



Belliss Engine for Belt Drive.
Air Compressors, Steam Turbines, Diesel Engines.

Heenan & Froude Ltd.

Worcester, England

Heenan Electric Freight Truck —Capacity 1,500-2,000 lbs. Can be driven in either direction. Will do the work of ten men. Will stand rough usage. May we send you further particulars?

"D.M." Feed-Water Treatment DOES MORE

than Increase Boiler Efficiency and Save Fuel

"D.M." Reduces Boiler Maintenance Costs— ECONOMY

You Would Not Waste Fuel if You Knew (You Were)

Let us tell you how D.M. accomplishes all we claim, how it accomplishes more than any other boiler compound and why it

Does More

THE BOILER D. M. LIFE SAVER

"D.M." Boiler Compound is of vegetable origin and while it absolutely eliminates scale it also prevents pitting or corrosion—in fact it

Does More

Manufactured by: HOUSEMAN & THOMPSON, Ltd., Newcastle-on-Tyne, England

Sole Distributors for Canada.

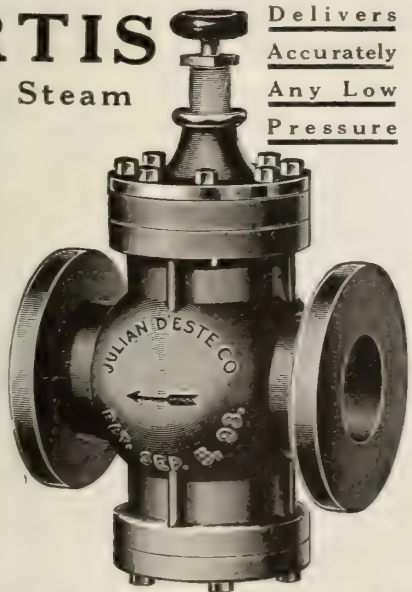
CURTIS

Improved Steam Pressure Regulator

Delivers Accurately Any Low Pressure

A compact, self-contained Regulator suitable for any boiler pressure. It delivers accurately and uniformly any lower pressure from one to within a few pounds of the initial pressure.

It has no levers, weights or projections; no glands or packing; no drip or leak of steam or water. Use it for efficient service on steam-heating apparatus, slashers, jacket kettles, air or water pumps, pulp mills, etc.



The Improved Steam Pressure Regulator is a lock valve, very simple and sensitive. Send for descriptive pamphlet.

Concentrate First on the Wastes that you can Stop at Small Cost

Benjamin Franklin once remarked that "Little leaks will sink a big ship."

And it's the little, inconspicuous leaks that are cutting down the profit margin in many manufacturing plants to-day. Because they are not spectacular, because they don't seem to amount to much, they are allowed to run on, adding their share day by day to the wrong side of the ledger.

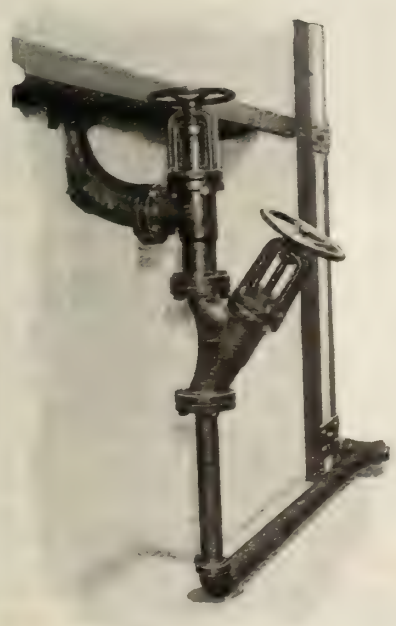
In this class come defective blow-off valves. A blow-off valve is a seemingly unimportant piece of equipment. Its cost is comparatively small—yet it may be the means of saving or wasting many times its cost each year.

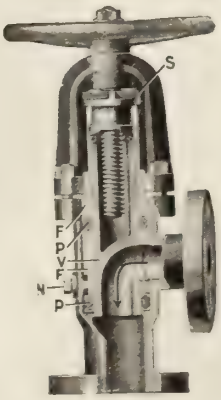
YARWAY SEATLESS BLOW-OFF VALVES are reducing fuel waste and increasing profits in thousands of plants. Their patented "no-seat-to-leak" construction gives them long life and permanent tightness.

"The Solution of the Worst Boiler Room Problem" contains full descriptions of this valve and the YARWAY DOUBLE-TIGHTENING VALVE, frequently used with it in tandem. Prices and comments of users are included, too. Tell us where to send your copy.

YARNALL-WARING COMPANY

Mermaid Lane & Ardleigh St., PHILADELPHIA





Send for celluloid model illustrating operation of the YARWAY SEATLESS BLOW-OFF VALVE.

Angle and straightway types of the YARWAY SEATLESS BLOW-OFF VALVE on one line in the plant of the New York Consolidated Card Co., Long Island City—an unusual installation to take care of special conditions.

A Time Clock *and* Recording Thermometer in ONE

Unvarying Accuracy

As can be readily understood, the most important factor of any Recording Thermometer is its actuating system. The very life of the Recorder lies in this system, and unless it be **perfect in all respects**, satisfactory records will not be obtained. Each "Columbia Recording Thermometer System" is built according to a rigid specification and under painstaking inspection. It is then

Tested and Seasoned

from two to three weeks by a "cooking" process. In this process, the system is subjected to a temperature considerably in excess of the maximum chart reading to insure the required ruggedness and capability. It is also subjected, as nearly as possible, to the same conditions under which the Recorder will be used in actual service. The system is checked for accuracy innumerable times during the testing period.

A perfect Recording Thermometer System is thus secured and to this must be given the credit for the high reputation the "Columbia" has won for unvarying accuracy and long life under all conditions.

First Find Your Coal Leaks

Bailey Boiler Meters Tell You

You can't eliminate coal leaks until you locate them. The only way to remove coal bill worries is to find the leaks and then go about eliminating them. Instinct will not tell your firemen just how well each boiler is burning the coal fed to it. The best they can do is guess.

Bailey Boiler Meters enable them to know exactly by showing the Steam Flow, Air Flow and Flue Gas Temperature—on the one chart. A lagging boiler is shown up. The meter tells whether excess air, fouled tubes, broken baffling or choked fires is the cause. There is no guess work—the facts are right before them all the time.

Write for bulletin No. 42.

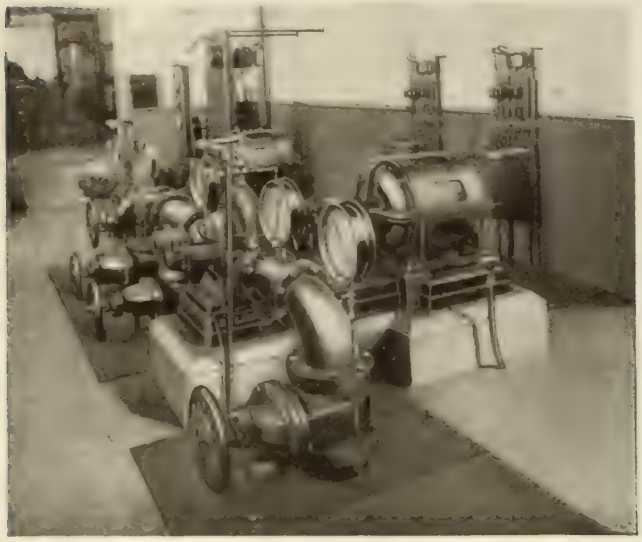
Collingwood Uses De Laval Motor Driven Pumps for Both Domestic and Fire Service

THE two De Laval motor driven pumps in the photograph were installed by the City of Collingwood, Ont., to provide both domestic and fire service. The pumps are each designed to deliver 1,200 gal. per min. against 165 ft. head at 1,740 r.p.m., but the piping is so arranged that the two pumps can be operated in series to give 330 ft. head.



De Laval centrifugal pumps are ideal for electric drive because of their high efficiencies and their power-limiting characteristics. The size of the motor can be selected to give the highest efficiency at the normal delivery of the pump, and the motor will not be overloaded even though the pump be allowed to discharge free against no head. This is also favorable to high power factor in induction motors, as is likewise the low starting torque required.

All De Laval pumps are guaranteed as to efficiency, capacity and power characteristics, and each unit is tested before it leaves the shops. The pumps are so designed that all working parts can be examined by lifting the casing cover and without disconnecting the piping. Parts subject to wear, such as bearings, shaft protecting sleeves and wearing rings, are easily renewed, as the pumps are interchangeable throughout, being manufactured to limit gauges.

State your pumping requirements so that we may send specific information.

GARLOCK PACKINGS

BETWEEN THE COAL PILE AND THE ENGINE

At this time more than any time in the history of engineering, highest efficiency is demanded. A blown out gasket can shut down a plant just as surely as a broken piston rod. Every leaking manhole joint or pipe flange represents a distinct loss, and it has been demonstrated by scientific experiment that there is no limit to the loss caused by undue friction on piston rod and valve stem packed with an inferior packing, and the constant use of a wrench in attempting to stop leaks at rod glands. Let Garlock No. 950 Gasket, cut from No. 900 Sheet Packing, reduce the loss between coal pile and engine.

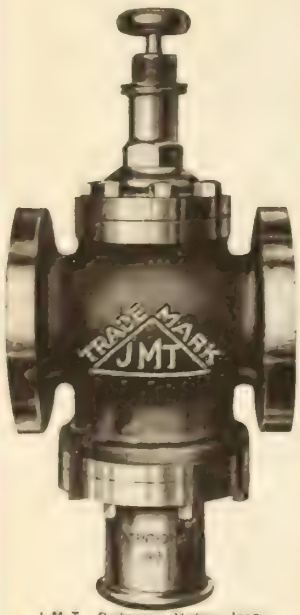
Pressure Reducing Valves

Efficient — Reliable

J.M.T. Flanged Reducing Valve.



J.M.T. Reducing Valve—Iron Body Bronze Mounted.

Non-Equalizing

Extremely Sensitive

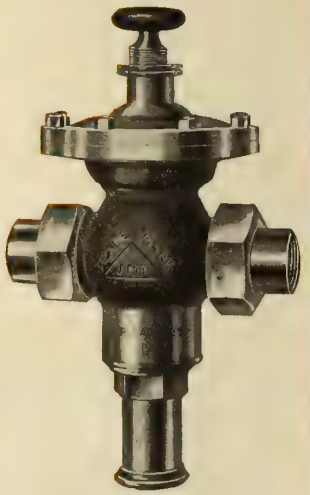
Nothing could be more positive than the action of the J.M.T. Pressure Reducing Valve in which the low pressure is controlled by the low pressure steam. When the desired low pressure has been obtained the low pressure steam closes the valve. Its simple, automatic effectiveness is the result of years of experiment.

J.M.T. Reducing Valves are made to suit every requirement and are sold with the well-known Morrison guarantee.

"Every Installation is a Demonstration of Merit"

Our Monthly Bulletin will interest you—let us put your name on our mailing list.

J.M.T. Reducing Valve, differential type, iron body.



J.M.T. Reducing Valve—Low Pressure.

For reduced pressures under 5 lbs. per sq. inch. The large diaphragm provides ample power to operate the valve on very low pressures and make the valve sensitive to the slightest change in the reduced pressure.

Multiple retort efficiency with single retort simplicity!

THROUGH the application of the unique "Lateral Retort" principle it has been possible to incorporate the functions and proved advantages of under-feed multiple retort firing in a stoker that is structurally equivalent to a single retort side cleaning stoker.

Translated into dollars and cents this ideal combination insures the fuel economy and overload capacity of a high duty multiple retort stoker, at a moderate first cost and low installation cost made possible by unequalled simplicity and the fact that no basement space is required for ash pits.

The views above illustrate the unique design and effective operation. Coal is fed by successive stokes of a ram into the main retort. It is then distributed into the retorts which branch at right angles—the *lateral retorts.*

This method of distributing fuel should not be confused with ordinary side dump stokers in which the coal is overfed from the main retort onto side grates. The coal is *under-fed* in the *lateral retorts* just as definitely as in the main retorts. Consequently it is always thoroughly volatilized and burns as coke.

Briefly summarized, the more important advantages of this stoker are:

The multiple retort effect—Coal is under-fed to the lateral retorts which are separately controlled both as to length of stroke and timing of stroke. This insures an even fuel bed and ideal flexibility.

Heavy overload capacity—The *lateral retort* design provides a large reserve fuel capacity insuring complete distillation of volatiles and proper coking even when heavy overloads are carried.

Low initial and installation cost—The extreme simplicity permits a moderate first cost, and the side dump construction does away with basement ash pits and expensive excavation. For this reason the "Lateral Retort" Stoker is adaptable to any conditions in existing plants.

Low maintenance—The *lateral retort* construction permits a simple, rugged construction; only two simple steam cylinders and a few rugged moving parts buried deep in the green coal at the bottom of the retort where they cannot burn out.

The construction and advantages of this stoker are thoroughly covered by a new catalog. Ask for it.

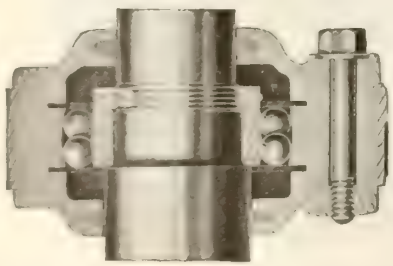
Fairbanks-Morse Ball-Bearing Motors Reduce Power Costs

The greater economy of Fairbanks-Morse Ball-Bearing Motors accounts for their extensive use throughout the world.

These ball-bearing motors have set a new high efficiency standard in saving power. The bearings, packed in grease, reduce friction and assure continuous operation.

The one-piece solid rotor winding with cast-on end rings, insures greatest electrical efficiency by preventing arcing due to loose rivets or screws, and eliminates costly repair bills.



They maintain alignment under the heaviest gear, chain or belt pressure because of the great strength and rigidity of the solid, one-piece frame.

Investigate the economy of Fairbanks-Morse Ball-Bearing Motors before buying.

Write our nearest branch for any information you need.

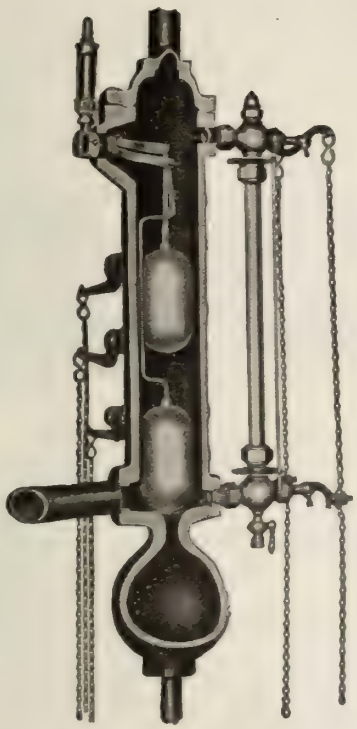
no engineer enjoys the job of reporting why a boiler in his plant has exploded



This shows you the "insides" of the Reliance Column. Our new catalog is fully illustrated with sectional views of this kind. Have you sent for your copy?

WHEN one of your boilers lets go with a vicious roar, smashing the neighborhood into rubbish, there is little personal satisfaction in it for you in making your report on the loss from the accident and the cause of it.

"Low water level, not detected in time."

A Reliance Safety Water Column would have set a whistle shrieking to snap the fireman into action; it would have flashed an electric signal to you to tell you trouble was afoot in the boiler room. There would have been no explosion. Instead, the fireman would have been called to account for letting the water get low enough to blow the whistle.

A Reliance costs so little and gives such dependable, valuable service that you can't afford to be without one on every boiler.

83% are Reliance

A questionnaire sent out to the power plants of Ohio shows that 83% of all the safety water columns in use in the state are Reliance. It is our estimate that fully 80% of all the safety water columns in use in the United States and Canada carry our name.

LINK-BELT POWER HOE (IMPROVED DRAG SCRAPER)

The Link-Belt Power Hoe is an effective arrangement for storing and reclaiming coal, sand, gravel, or any loose material in either open or covered storage. It is low in both first cost and operating cost.

It involves principles that are new to this class of implement which not only prevent overloading or "digging in" but also eliminate the necessity of dumping at the end of the haul.

The movable anchor and balanced pulley blocks allow the use of one-third the number of anchor posts required by similar devices of this kind.

The Link-Belt Power Hoe is adaptable to storage areas of any shape, where the haul is not more than 400 feet. Send for the Link-Belt Power Hoe Book No. 444.

Nonpareil Cork Covering installed in 1912 in the basement of the Avondale Store of the Kroger Grocery and Baking Company, Cincinnati, Ohio.

After Ten Years— As Good as New

ONE of the reasons why Nonpareil Cork Covering is so economical is that it lasts so long. Here, for instance, is a covering job that was done in 1912. Yet it looks like new and *is* like new. There isn't a break in it, and no reason why it should not be just as sound in 1932 as it is to-day.

Each year, this Nonpareil Cork Covering pays back its cost in refrigeration saved, with no more upkeep expense than an annual coat of asphaltic paint and an occasional tightening of loose wires.

Compare such insulation with the coverings you sometimes see dripping with moisture or bulging with frost after two or three years of service. Covering that absorbs moisture loses quickly whatever insulating value it has when dry, and soon disintegrates. Not only does it *not* repay its cost at all, but in a very short time the original cost and more has to be spent again to tear off and replace the worthless material.

Why experiment and lose when you can be certain and profit? Ask the Kroger Company if they would even consider anything but Nonpareil for *their* cold lines.

Have you lines that need to be insulated or reinsulated? Write for information on Nonpareil Cork Covering and save yourself money and trouble.

When Engineers Get Together—

and talk of long-living steam specialties they are sure to spend considerable time telling of their happy experiences with the Fisher line.

FISHER REDUCING VALVES

for instance, have conclusively proven their long-lasting reliability in all parts of the world. No matter what kind of work or what kind of conditions they go quietly and efficiently about their jobs. Dependable, that's what they are!

Fisher Reducing Valve (Type 11-A) is a stock reducing valve with an expanded outlet. These valves are made in a wide variety of inlet and outlet size combinations. We are sure to have one in stock exactly suited to your requirements.

Controlling pressure is taken from the low pressure main at a point where there is an average low pressure insuring accurate control.

The inner valve is semi-balanced and double-seated. It operates without hammering or chattering.

Have you seen our interesting FLOW CHART? It shows just exactly the best Fisher Reducing Valve for any desired pressure. Ask for Bulletin 201.

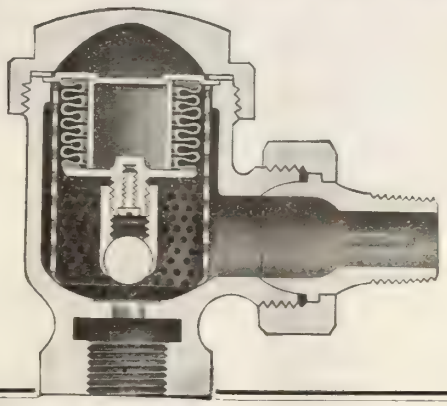
Making 100% Heating Installation EFFICIENT



In these days factory owners are inquiring more closely than ever into operating costs. With coal at present high prices, your heating installation will be judged on the saving of fuel effected. And in order that it may operate at 100% efficiency as a whole, it must be properly trapped.

All radiator traps are not alike. To be positive that the condensate will find immediate egress, install the

Radiator Trap

SARCO

For instantaneous, positive, reliable action, the Sarco is in a class by itself. A very small quantity of condensate in the trap cools the thermostatic element, causing the vapor in the drum to return to its liquid state. This immediately restores the vacuum, which in turn causes the element to contract and open the valve, discharging the water and air to the return. Steam following, at once reverses the action, closing the ball valve again.

The total lift of the ball valve from its seat, about ¼", permits of a free discharge, while its pressure on the valve seat, on return, is such as to prevent the escape of steam.

No other element, either flat disc or corrugated type, has such a long life as the Sarco element, due to the spiral (not annular), corrugations which distribute the valve movement over practically the entire drum. When you install the Sarco you get year-in-year-out durability as well as efficiency.

Drop us a postcard for illustrated Booklet J-103.

BELDAM'S

LASCAR and ALLIED

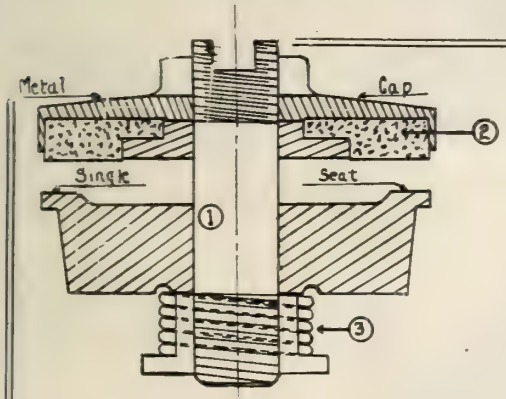
Asbestos Packings

Their Efficiency Means Real Economy

This is not an empty claim; it is backed by actual experience of engineers in practically every country in the world. The Beldam line of Patent Semi-Metallic and other Packings is constructed to one end—Efficiency and Economy in the Engine Room. It is made to suit specific conditions by engineers who appreciate the requirements, and as such it is guaranteed.

"Lascar" V Packing is characteristic of this efficiency. It consists of a single V-shaped bar of white metal securely fastened in its cushioning of the highest grade asbestos. It is extremely flexible and exactly takes the shape of all rods. Its continuous bearing surface of white metal reduces friction on the rods to a minimum.

It is particularly adapted for the highest steam pressures and has the advantage of great durability, saving much time and labor.



There Are Only Six Parts To This ROBINSON Valve

Perfect seating, maintenance of alignment and durability are assured in this Robinson Pump Valve; as the stem, instead of being fixed with relation to the seat, moves in long bearings of metal to metal.

All working parts consist of metal in contact to metal and all joints where leaks might occur comprise metal in contact with packing.

There are only six parts—less than half the number used in valves of the same type and comparable in efficiency.

THIS CONCRETE DAM
successfully met a severe test

CANADA is justly proud of her "white coal." The development of the Dominion's water power has employed the highest skill of the engineering profession—and in this development concrete and reinforced concrete construction have played an important part—both as regards publicly-owned and privately-owned water rights.

Our illustrations are from photos of the Southern Canada Power Company's plant at Drummondville. Quebec.

The top view shows the completed dam—and the arrow points to the location of the Power House.

The lower view illustrates the splendid resisting qualities of concrete. The breaking up of the ice nine days before the completion of the work unexpectedly flooded the dam; yet the structure was uninjured by the severe strain thus suddenly placed upon it.

Montreal Cold Storage Warehouse Plant

This Plant is Among the Outstanding Examples of Storage for Perishable Goods That Can be Found Anywhere in the World—In Its Construction, Canadian Brains and Material Predominate

THE magnificent Cold Storage Plant now being completed by the Harbor Commissioners of Montreal will be, when completed, one of the finest undertakings of its kind in the world. It will be of national importance to Canada and of great value to the harbor of Montreal.

The plant consists of two buildings; the warehouse where food products from all parts of Canada and certain parts of the United States, in the form of fruits, eggs, cheese, meats, fish, vegetables, etc., will be received, refrigerated and held in suitably-preserving temperatures until shipments abroad or elsewhere are required; and the power house, where all mechanical equipment is being installed for the cooling of the refrigerant necessary to maintain the preserving temperatures in the various cold rooms of the warehouse.

Each building is of very handsome and massive design, of fire-proof construction, and in every way a credit to the harbor. While not having as large a floor area as one or two other cold storage warehouses built during the war, yet this warehouse on the Montreal Harbor front will contain features in connection with its equipment which will place it ahead of any other cold storage warehouse.

After it was decided to build the plant, the Harbor Commissioners engaged the services of Major R. Percy Sims, as Consulting Refrigerating Engineer, who has had a most extensive experience in this class of engineering in all parts of the world. He was personally responsible to the commissioners for the preparation of all the specifications and plans of all the equipment in the plant, and has also personally superintended its complete installation.

In this work, Major Sims' main object was to so design and arrange the plant that it should operate at the highest efficiency, and provide such equipment as would enable the greatest confidence to be established between the owners and shippers of the goods stored in the warehouse and the Harbor Commissioners as the operators of the plant, and to insure against useless and costly litigation, often caused through misunderstanding.

Special Features

There are many special features in connection with the equipment of this cold storage plant which are worth describing. One of the special features is what is technically termed, the air-conditioning of the rooms. In most cold storage warehouses, the condition of the air in the rooms is neglected and, considering that they contain food for public consumption, it is often very impure. Most of the food products stored give off gases, odors, heat, moisture, etc., which if not promptly removed, are

General view of rear of plant showing trackage.

detrimental to the proper preservation of the food. In a few cold storage warehouses the air-conditioning of the rooms has been spasmodic, incomplete and half-hearted, with the result that there is very little data available on the subject under low-temperature conditions. In the Montreal Harbor Cold Storage Warehouse, each room will be equipped so that the air in that room will be changed as often as its contents require and before the air is returned it will be thoroughly washed, brought to the proper humidity, purified by the introduction of a proper quantity of ozone, and slightly reduced in temperature to prevent its condensation as it enters the room. There will be a separate air-conditioning room on each cold storage floor, due to the great difference in the temperatures of the various floors. The introduction of the ozone into the washed air, previous to its return, not only purifies the circulating air but also destroys such germs or impurities as may exist in the room in which it enters. It is believed that this special air-conditioning feature will be fully appreciated by the owners of the goods stored, as soon as they realize its advantages.

Thermometer Installation

Another special feature in the equipment of the warehouse is the completeness of the thermometer installation, relating to the temperature of each of the cold rooms, and also that of the circulating refrigerant. Each room will be equipped with an indicating thermometer, the bulb being placed in a suitable position inside the room, and the indicating dial attached to the division wall of the room in the distributing corridor. This indicating thermometer will be for the use of the floor operator, and will enable him to ascertain the temperature inside the room without entering. In addition to these indicating thermometers there will be a complete system of recording thermometers, with continuous charts, situated in the office of the general superintendent of the warehouse, which will avoid disputes between the owners of the goods stored, and the operator of the building. Many hundreds of thousands of dollars have been paid by cold storage companies, in order to avoid litigation because they have not been able to disprove allegations by the owners of the goods stored that improper temperatures have been maintained. On the other hand, this complete recording system of temperatures will insure a great deal of extra confidence, on the part of the owners of perishable produce using the warehouse, because they will feel that owing to this continuous record being kept greater care will necessarily be exercised by the operators of the warehouse. The contract for this work has been placed with Messrs. Peacock Bros., Ltd., of Montreal.

The only refrigerant to be used in this new cold storage warehouse is a solution of chloride of calcium, of a density which will prevent its congealing under temperatures considerably below the normal temperature required for the refrigerating of the rooms. This calcium chloride solution will be conveyed from the power house to the basement of the warehouse through steel pipes having an internal area of over 170 square inches, from which it is taken to the various cold storage floors through four 8 in. risers, arranged in such a way that the pressure of the supply on each floor is equalized. The cooling of the rooms is accomplished by circulating the solution through 2-inch. galvanized pipe coils suspended from the ceilings, after which it returns to the power house. Several hundreds of thousands of feet of this 2-inch galvanized pipe have been installed in the rooms for this purpose.

A Heating System Necessary

In a cold storage warehouse, it is the popular idea that a heating system is not required, yet in a building of this character there is much space which should be equipped with heating apparatus. In the harbor warehouse, there is a steam heating system which has cost nearly thirty thousand dollars, the steam for which is generated in two Victory water-tube boilers, each of 120 horse-power, made by the Robb Engineering Company of Canada, Amherst, N. S. The whole of the 2nd, 3rd and 8th floors, the offices on the 1st floor and the distributing corridors of the cold storage floors have been completely equipped with a Webster vacuum heating system installed by the Garth Company of Montreal, the special Webster equipment being furnished by Darling Bros., Limited, of Montreal.

Automatic Sprinklers

Throughout the warehouse there is an automatic sprinkler system. Although the building itself is, practically, fireproof, yet it will contain goods of an inflammable nature and worth millions of dollars. By the installation of an automatic sprinkler system, the insurance rate is so reduced that the entire cost of the installation is paid for in a few years by such reduction, apart from the continuous protection to the building and its contents.

In the past, there has been a consid-

erable amount of trouble with automatic sprinklers in low-temperature buildings, especially freezers, due to the condensation of the compressed air in the sprinkler piping, causing the stoppage of the pipes by ice. Major Sims gave this matter a special amount of study with the result that this new cold storage warehouse is equipped with a completely new system of automatic sprinklers on all floors subjected to temperatures below freezing point, operating by a solution of calcium chloride, the same as is being used for the cooling of the rooms. There are four overhead stor-

age tanks, situated in towers above the roof, each containing 15,000 Imperial gallons of calcium chloride solution. In the event of a fire occurring of such magnitude that this storage supply of 60,000 gallons of solution is not sufficient to deal with it successfully, the city water supply is automatically turned on to the sprinkler system, through the operation of two 8-inch automatic deluge valves. As, however, calcium chloride solution of the density to be used has an extinguishing effect of not less than 600 per cent. higher than that of water, it is the opinion that the fire which cannot be successfully extinguished by this large quantity of solution will be beyond the extinguishing power of the city supply.

Another great feature, and one which is also entirely new, is the special alarm system which has been installed throughout the building. This consists of little devices attached to the ceilings of the various cold rooms, which operate at a rate of rise of the temperature of the rooms, at or above fifteen degrees Fahrenheit per minute, and which operate a red signal light in the corridor adjacent to the room, also a loud fire gong in the centre of the corridor of that particular floor, and a fire gong and floor-indicator in the offices of the general superintendent, and in the power house. A sprinkler head operates at a temperature of about 165 deg. F. and in a room of, say, 10 deg. F. it would take about ten or eleven minutes for the head to operate with the rise at the rate of fifteen deg. per minute; whereas, with the special alarm system above described, the alarm is given almost instantly, even if the rise in the room is only one degree, so long as the rate of rise per minute is fifteen degrees, thus enabling the operators either in the warehouse or the power house to ascertain the locality of the fire, and effectively deal with it by means of the corridor hydrants, even before the automatic sprinklers may be required to operate. While on the subject of fire protection, it should be noted that all the elevator shafts, stair-shafts, and other possible means of creating a draught to assist a fire, are each provided with an automatically closing door, operated by this same device which works at a rate of rise in the surrounding temperatures of fifteen degrees or more per minute. In addition, the building is provided with one main fire-wall, absolutely dividing one half of the building from the other half, to prevent the spread of fire. All windows throughout the building, are provided with wired glass. The whole of the work entailed by this automatic sprinkler system and the special alarm system has been installed by the Automatic Sprinkler Company of Canada, Limited, of Montreal, with the exception of the overhead tanks which were furnished and erected by the Horton Steel Works, Limited, of Bridgeburg, Ontario.

Cold Room Insulation

The insulation of the cold rooms in a building of this nature is a very costly and a very important feature. Initially, only four floors are at present insulated, but the building has been designed for an extension of the insulation as the business warrants. This insulation consists of layers of compressed cork-board, which are laid against the walls and ceilings in cement, the aggregate thicknesses varying from 4 to 7 inches, according to the position of the rooms and temperatures to be maintained. This insulation contract was divided between two firms, The Armstrong Cork and Insulation Company, of Montreal, and the Canadian Corkboard of Port Colborne, Ontario, the total cost amounting to nearly $200,000,000. All the brine mains inside the warehouse, also those in the power house are covered with four inches of compressed cork, this work being done by the Armstrong Company at a further cost of nearly $70,000.00. It is not often understood how important it is in a plant of this character, to have the highest efficiency in regard to the insulation of the rooms and the brine mains.

MAJOR R. P. SIMS,
Montreal, Canada.
Constructing Engineer, under whose supervision the plant was constructed.

Elevator Installation

Provision has been made in the warehouse for eight electric freight elevators and one electric passenger elevator. At present, only four of the freight elevators have been installed, and also the passenger elevator, these being manufactured and erected by Darling Bros., Ltd., of Montreal. The freight elevators have a platform 9 ft. x 12 ft., and have a normal capacity of 12,000 lbs. when running at a speed of 90 ft. per minute. They are of the overhead, single-wrap traction type operated by a special high-torque 40 h. p. motor controlled by an automatic elevator controller with car-switch in the car. Each elevator is fitted with two powerful magnet-operated brakes, and also with hand-controlled wedges on the floors for securing electric or other trucks in position during travel of the car. The electric passenger elevator has a normal capacity of 2,000 lbs. when traveling at the rate of 200 ft per minute. The size of the platform is 5 ft. x 6 ft., and is also of the overhead traction type.

The whole of the cement used in these structures was supplied by the Canada Cement Company of Montreal, and the reinforcing steel was supplied by the Steel Company of Canada, the cost of this alone amounting to $180,000.00. The face brick was supplied by the Inter-provincial Brick Company and the terra cotta tile by the Montreal Terra Cotta Company.

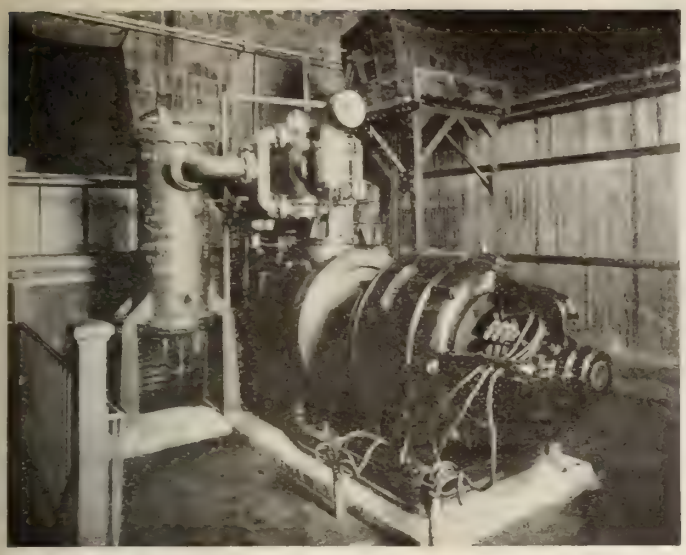
The buildings each stand on a concrete slab, supported by concrete piles inserted by the Canadian McArthur Concrete Pile Company. The soil on which these buildings stand is partly sand and partly clay, and the piles were driven through this until they reached hard pan or shale rock. The total number of piles driven amounted to 2,942, the total lineal feet being 55,551, the diameter of each pile being about 16½ in., and the load on each pile is about 60 tons.

One of the most important features of the cold storage plant is the arrangement by which ten standard refrigeration cars can be run end-on into the warehouse and closed in by Kinnear Rolling Steel Doors, so that the cars can be filled or emptied without any undue loss of refrigeration either in the goods or in the cars, and it also obviates the disadvantages due to cartage.

The Power House

The power house is situated east of the warehouse and is somewhat unique in design, on account of the lack of ground space due to the requirements of the harbor railroad tracks. At present, there are three horizontal, belt-driven, Linde ammonia compressors installed, each having a normal refrigerating capacity of about 150 tons per day. These compressors are each driven by an electric motor of 250 horse-power, two of the motors being made by the Canadian General Electric Company, and one by the Canadian Fairbanks Company, the latter being of ball-bearing type. A fourth ammonia compressor will be installed at a later date and provision has been made in the design of the power house to enable an additional two ammonia compressors of the same size to be installed, should the business of the warehouse warrant such extension. In the meantime, this space is being used as an electric sub-station, for transforming the alternating current received in bulk from the Montreal Light, Heat & Power Company into direct-current for use in connection with the traction requirements of the harbor railways, and it also contains all the switchboard equipment for the cold storage plant.

In each of the ammonia compressor rooms, and also in the electrical sub-



View of deep well air compressor.

Interior view of one of beef rooms.

station room, there has been installed an overhead traveling crane, each of a normal lifting capacity of 12½ tons. These cranes were of particular advantage during the erection of the machinery and will always be of use whenever it is necessary to carry out any repairs necessitating the lifting of any of the heavy parts of the equipment.

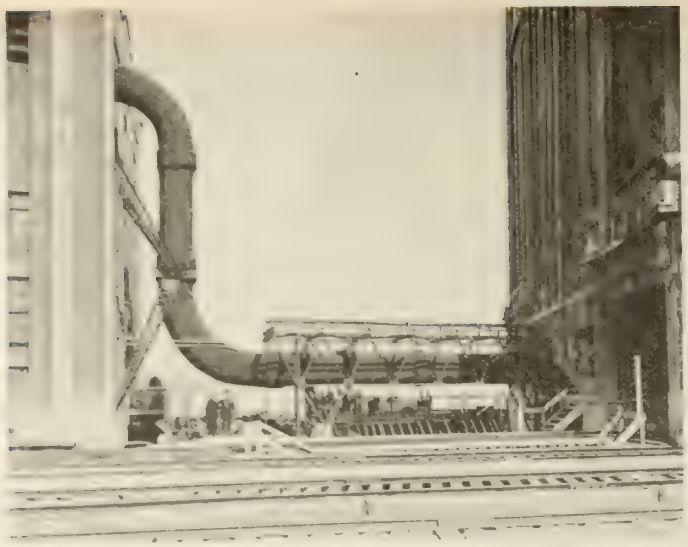
On the floor immediately above the ammonia compressors, there is a considerable amount of heavy equipment, chiefly in connection with the cooling and circulation of the calcium chloride solution used in the cold rooms of the warehouse. There are two large brine coolers, each consisting of a tank with 56 endless coils immersed in the solution. Each tank is about 36 feet long by 26 feet wide by 8 feet deep, and each coil consists of about 600 lineal feet of 1½ in. wrought-iron lap-welded pipe in one continuous length. The brine cooler tanks were fabricated and erected by the Dominion Bridge Company of Lachine, each tank weighing alone about 60 tons. The endless ammonia expansion coils were made by Mr. James Ballantyne of Montreal, all welding being done by the Thermit Process, and every coil being hydraulically tested to 650 lbs. per sq. in. The insulation of these large brine coolers is very heavy due to the very low temperature of the solution contained therein, this work having been done by the Armstrong Cork & Insulation Company. The cooling of the solution is accomplished by the expansion of liquid-ammonia into ammonia-gas inside the coils, and this ammonia-gas is then drawn out of the coils by the ammonia compressors, and thence delivered to the ammonia condensers. These brine coolers each contain approximately 210 tons of solution, which can be used as a reservoir for cooling the rooms in the warehouse for several hours, even if the compressors are stopped.

On this floor, also, there are at present installed four electrically-driven brine-circulating pumps, with provision for two more to be installed at a later date. Each of these pumps is capable of delivering 600 imperial gallons of calcium chloride solution to the warehouse per minute; they are of the Rees-Roturbo type, made by Goldie & McCulloch of Galt, and supplied by Ross & Greig of Montreal, the motors being made by the Canadian Westinghouse Company. This solution, immediately it leaves the pumps, passes through a Venturi meter, which indicates, registers and records the amount of flow. In addition, there has been installed a Bristol recording and indicating equipment by Peacock Brothers of Montreal, which continuously indicates and records the temperature of the solution as it leaves the power house, and also as it returns. These records of flow and temperature of the solution are of great assistance to the operating engineers, to enable them to detect, at a glance, any variation in the efficiency or operation of the plant.

On the brine-cooling floor also is an electrically-driven, high-speed, vertical air compressor, made by the Browett-Lindley Company of England and sup-

View showing 56 ammonia expansion valves.

View showing typical distributing corridor.



Brine mains from power house to warehouse.

[illegible] by Peacock Brothers, the motor being manufactured by the Canadian Westinghouse Company. This air compressor is used for the lifting of the water from the deep well outside the power house, and has a capacity of 350 cubic feet per minute, with a pressure of 125 lbs. per sq. inch when running at 390 revolutions per minute.

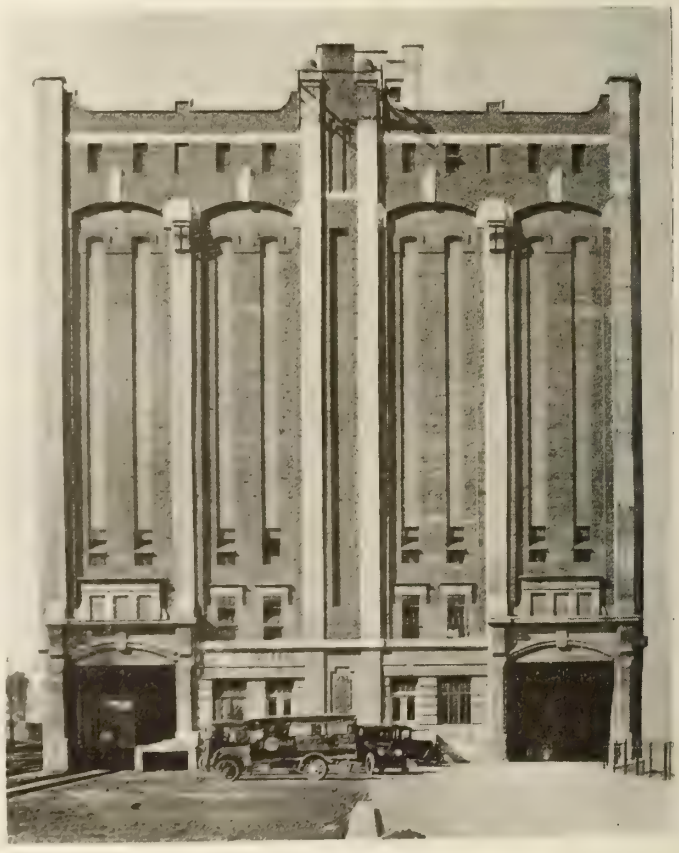
There is also on this floor a small ice-making tank, which is capable of making 5 tons of ice per day, in 100 lb. blocks. This ice will be used in connection with the tugs, stores, etc., run and operated by the harbor authorities.

On the roof of the power house, but surmounted by a double-deck cupola, are situated the ammonia condensers. These are of the atmospheric type, each of about 150 tons normal refrigerating capacity, of which there are three at present installed, with provision for an additional unit in the future. As the name implies, these condensers are for the purpose of condensing ammonia-gas into liquid ammonia. As previously described, the ammonia-gas in the expansion coils in the brine coolers is drawn out by the ammonia compressors, and is delivered under pressure into the coils of the ammonia condensers. Over these coils there is a continuous flow of cold water from the deep well, and it is the combined action of the pressure of the gas with the cooling effect of the water which causes the ammonia-gas to liquefy. As this gas liquefies, it runs by gravity into steel containers which act as reservoirs for the supply to the expansion coils in the brine coolers.

On a floor in the cupola, above the ammonia condensers, are situated two long water tanks for the distribution of the water for the condensers, and for other water supplies throughout the power house. These tanks are each 82 feet long, with a capacity of 21,500 gallons, and the water level will be automatically maintained by a supply from the deep well. These tanks were fabricated and erected by the Dominion Bridge Company.

The deep well is just outside the east end of the power house, it being 10 inches diameter by 1,100 feet deep. The water from this well will be pumped into a small separating tank in the basement of the power house by means of compressed air. The separator tank contains a series of weirs, which spread out the water in such a way as to separate the air from the water before it is pumped up to the two long distributing tanks over the ammonia condensers. Arrangements have been made for an adequate supply of water from the city mains to the distributing tanks, in the event of a failure of the deep well supply through temporary or other causes. The great advantage of the deep well supply for mechanical refrigeration is the difference in the average temperature of the water in the city mains, especially in the hot season of the year when the plant is working to its highest capacity. This difference of temperature of the water used on the ammonia condensers makes a corresponding difference in the pressure to which the ammonia-gas has to be compressed, resulting in lower power costs at the motors. This well was bored by the Wallace-Bell Company of Montreal and the pump was made by the Weber Pump Company of New York, and supplied and installed by the Garth Company of Montreal.

Almost all of the ammonia fittings in connection with this large plant were manufactured in Canada by the Crane Company, Limited, of Montreal. This company also manufactured and supplied a very considerable amount of pipe-work, mains, etc. The solution of calcium chloride, previous to its delivery into the brine coolers, is mixed by means of a specially-designed, electrically-driven brine mixer, furnished by the A. R. Williams Machinery & Supply Company of Montreal. In order for one to obtain an idea of the magnitude of this plant it should be noted that, for the initial charging up of the brine coolers, circulating coils and sprinkler system, it has necessitated the use of over 300 tons of granulated calcium chloride, all of which has been converted



View showing west end of warehouse.

General view of Montreal Harbor—showing Victoria dock and cold storage warehouse.

into a solution by means of this small electrically-driven brine mixer.

The whole of the reciprocating and rotary equipment of the power house has been installed with a gravity-feed oiling system made by the Richardson-Phoenix Company, of Milwaukee, and furnished by the A. R. Williams Machinery and Supply Company. By this equipment all bearings and other lubricated parts are furnished with a continuous supply of oil by gravity from a reservoir in the cupola over the power house, and after passing through the bearings this oil is automatically collected and passed through a filter in the basement, thus removing all foreign matter; it is then electrically-pumped back to the reservoir in the cupola, thus using the oil over and over again. Of course, there are certain losses in connection with this oil and it is bound to lose its effectiveness after a time; provision is therefore made for replenishing the reservoir, whenever necessary, with new oil.

All Canadian and British Work

It has been the desire of the harbor commissioners to make this cold storage plant not only one of great usefulness to the port and to the Dominion as a whole, but also to insure the design of the building to be one of credit to the harbor. The whole of the construction work in connection with the two buildings constituting the plant was carried out by the engineering department of the harbor; a work of considerable magnitude, and one to be justly proud of.

Exceptional care and thought has been exercised in the preparation of the plans and specifications of this cold storage plant in order that it shall be as perfect as modern engineering science and experience will permit. It has been the desire of the harbor commissioners and of the consulting refrigerating engineer that all material used on this great national undertaking should be strictly of Canadian manufacture, as far as it was possible and subject to the efficiency and cost of the plant not being impaired thereby. It is a source of much gratification that this desire has been carried out, and furthermore, the work of designing and constructing the plant and its equipment has been entirely undertaken in such a satisfactory manner by Canadian and British engineers and workmen. Major Sims was fortunate in having a very loyal and able engineering staff, and particular mention should be made of Mr. J. R. Dalkin, his direct representative on the work, also Mr. J. J. Dillon, who was in charge of the erection of the mechanical equipment, and Mr. F. J. DiBenga, the chief draughtsman on the work. Being of such a national character, owned by the people of Canada, there is no reason why the control and operation cannot be permanently and entirely in the hands of Canadians.

ENGINEERS AND THE POWER EXPOSITION

The National Exposition of Power and Mechanical Engineering to be held at the Grand Central Palace in New York from Thursday, December 7 to December 13, closing, however, on the intervening Sunday, is being planned in co-operation with the national societies interested in the economy of fuel and in the production and use of power generated therefrom.

The opening of the Exposition in the Grand Central Palace will take place on the closing day of the annual meeting of the American Society of Mechanical Engineers, and time has been set aside in the A. S. M. E. program so that members desiring may attend the opening exercises. Furthermore, the programs of the twenty sessions to be held at the meeting may reap the advantage of the technical discussions, and with the smallest possible expenditure of time, enjoy the novel and varied exhibits at the Exposition. A few of the subjects to be discussed at the A. S. M. E. meeting are:

Commercial Economy of High Pressure and High Superheats.
Feedwater Heating for High Thermal Efficiency.
Development and Use of Stokers.
Transmission of Superheated Steam.
Ash Removal—A Symposium of Modern Handling Methods.
Gears.
Power Required for Removing Metal.
Safety Valves.
Torsion of Crankshafts.
Pulsating Flow in Flow Meters.
Dry Vacuum Pump Tests.
Design of Flywheels.
Tests on Orifice Coefficients.
A Modern Works for the Production of Monel Metal Steam Table Research.

In addition, the A. S. M. E. Professional Divisions on Aeronautics, Ordnance, and Forest Products will hold sessions of general interest to the engineering profession.

The American Society of Refrigerating Engineers is to hold its meeting at the Hotel Astor for three days commencing December 5, and its members, as well as the members of the A. S. M. E., will be admitted to the Exposition upon the presentation of their membership cards.

The opportunity this Exposition offers for the power house operating man will also be grasped. The National Association of Stationary Engineers is perfecting plans for the various chapters to visit the Exposition in a body. In addition, the New York Building Superintendent's Association, 600 strong, will attend in a body and they will be received by the officers of the N. A. S. E.

The list of exhibitors already assures the fact that the Grand Central Palace, with its remarkable facilities, will house the greatest exhibition of power plant equipment ever contemplated.

(Continued on page 35)

Large Variety in Appliances Available

The Manufacturer Has Placed at the Service of the Engineer a Large Number of Excellent Devices. The Engineer Should Be Familiar With Them, and Able to Advise Intelligently on Their Use

By T. H. FENNER

WHILE there are a certain number of industries which find it possible to obtain all their power from central power stations, either government owned hydro electric, private hydro electric, or steam generated, there are practically none that do not use steam in some part of their work. It may be that it is only for heating the building, or the office, in the cold weather, but it has to be there. The generation of steam implies a boiler, and the presence of a boiler necessitates auxiliary equipment, even if that be only a small injector. With this as the elementary form of steam using industry, we progress all the way to the factory which uses steam as a power generator, steam in process work, and steam for heating. The steam for heating may be a by-product of the steam used for power, and the process steam may also, to some extent, be of the same nature. In the range of the passage of the steam from boiler to engine, through the exhaust piping, and other steam piping, back to condensate which may or may not be returned to the boiler, there is a great variety of equipment installed. It is somewhat of a problem for the factory executive to know where the use of appliances changes from a necessity to a luxury, and it is on this point that the engineer in charge of the plant should be able to give him correct advice. If the installation is a new one, it is probable that all the equipment will have been specified by the consulting engineer, but there are many plants which start their existence on the scale of the elementary boiler plant we have already mentioned, and gradually grow up to the highly complicated form just alluded to. Sometimes the engineer who saw the inception of the plant grows with it, in every sense of the word, but there are other cases where the original incumbent of the position becomes overawed with the extent of the growth and retires. We have seen a number of instances of both conditions.

Elementary Plant Has Problems

In the very small plant consisting merely of a boiler and a means to feed it, a problem often arises which is a puzzle to the owner, and often to the boiler attendant. Shall he use a pump for feeding, or shall he use an injector? Well, what are the advantages and disadvantages of each piece of apparatus, and what is the situation in regard to the feed water? Can the condensate be used again for feed water, or has the feed to be made from fresh water entirely? Is the boiler driving an engine, or is the steam used entirely for heating? Perhaps the steam is being used merely for heating hot water, in which case it is discharged directly into the tank to be heated.

If the feed water has to be entirely fresh water and no condensate is available for feed and there is no engine exhaust available for heating, then an injector represents the best method of feeding on the small boiler up to 50 horse power. It is compact, has no moving parts, and has the great advantage that there is practically no loss of heat incurred in the act of getting water into the boiler. The heat of the steam used to operate the injector is all returned with the feed water. It is positive in its action when handling cool water, and has practically nothing to get out of order. It can be operated with low steam pressures.

If, on the other hand, exhaust steam is available for heating the feed water, or the condensate can be returned to a hot well from which it can be pumped at fairly high temperature, or if a receiver can be used which can be placed above the suction of a pump, then a pump becomes a better means of feeding than the injector. Of course, when large sizes of boilers are being used, an injector is out of the running as the size required would make it cumbersome, and furthermore, it has not got the flexibility of the pump. If the boiler is used for purely heating purposes, then the best arrangement is either feeding by means of gravity return traps, or a vacuum return system and a pump and heater, in which the exhaust from the feed pump can be used to raise the temperature of the condensate from 150 to 180 or 200 degrees. In the case of the pump handling returns through a receiver, there is the disadvantage that in many cases the condensate is cooled by the admission of cold water from the city service mains, and this is resorted to also in the case of the vacuum pump in vacuum return systems. In the case of the vacuum return system the other advantages outweigh the small amount of heat lost by the use of the small condenser on the pump. When gravity return traps of the tilting type can be used they represent the ideal way of boiler feeding, as they combine the advantages of the pump with that of the injector. The drawback to most of the tilting traps is the double caused by the packing of the trunnions, which requires considerable care and maintenance if the trap is to function properly.

It can thus be seen that even in the small boiler room there is scope for the use of engineering common sense in deciding on the type of equipment which shall be installed.

Hand Or Mechanical Stoking

The question of whether the boilers shall be equipped with mechanical stokers or shall be hand fired is one that largely depends on the size of plant. If a plant has only one boiler then it is certain that there can be no saving of labor by the installation of mechanical stokers, as an attendant will be required in any case. In the small boiler plant it is possible to instal one of the many excellent hand-operated dumping or moving grates, and while these do not eliminate the fireman they certainly tend to greater fuel economy. By relieving the fireman of the necessity of cleaning fires they make his work much easier and enable him to devote some of his time to keeping the boiler room in better shape. Cleaning fires is a task that puts a terrific strain on the human frame and takes more out of a man than several hours of ordinary firing would do. Where only one man is employed, as is so often the case, installing a hand-operated stoker is worth while even if the economy effected is of the slightest. The investment is itself only slight, and will pay dividends in the shape of a more contented fireman and a better kept boiler room.

When the larger plant is in question the installation of mechanical stokers should be considered from several viewpoints. First there is the return in the investment due to saving in labor; second, the saving by being enabled to use a lower grade of fuel; third, the saving due to better combustion and general efficiency, and in some cases saving in first cost by the possibility of installing a smaller boiler plant. This last is, of course, due to the mechanical stoker being capable of carrying heavy overratings for short periods, such as peak loads in a central station. Many manufacturing plants are also subject to heavy peak loads of an hour or two duration, notably in those cases where the full lighting load on dark days comes at the same time that the cupola is put into service for making the daily cast. In general, it may be said that in any plant of 500 horse power or over, the mechanical stoker is justified.

Coal and Ash Handling

The method of storing coal, the capacity of the bunker immediately adjacent to the boilers, the capacity of general storage, the location of the general

storage in relation to the service bunker, and the receiving period will all be factors in determining the necessity of coal-handling apparatus in the first place, and the type of machinery in the second place. Many small plants are so situated that the maximum reserve that can be carried is only equal to three or four days' supply, and the consumption is so small that one man can very easily attend to the delivery of coal to the boilers and the removal of ashes. If such a plant is below the street level the coal can be usually dumped direct from a cart into a bunker immediately communicating with the boiler room, and there is no problem in the receiving of coal. The removal of ashes from the ashpit and in the case of h-r-t boilers of the deposit from the combustion chambers may constitute a necessity for some type of conveyor. This can in most cases be met by the installation of a simple I beam with a travelling hoist either electrically or pneumatically operated, or fitted with a differential chain block. By this means the buckets can be raised from boiler floor level to the street level, or high enough above it to allow dumping into a wagon, with the attention of the same man who handles the coal. This type of equipment is cheap to instal, and costs practically nothing for upkeep.

In cases where there are several boilers and hand-firing is used, the same type of trolley carried right along the boiler fronts at a convenient distance from the front for the firemen and with switches communicating with the bunker will enable one man to keep the firing floor well supplied and also look after the ashes. The ordinary method of handling coal from bunker to firing floor with a barrow is, except in the case of extremely small plants, a wasteful one in both labor and coal. The amount of coal that is spilled from wheel barrows and ground up on the floor of bunker and boiler room amounts in the course of a year to a very appreciable total.

When considerations of space make it necessary for an overhead bunker to be installed, then of course coal handling apparatus becomes compulsory. This will usually be of the bucket or flight conveyor type and will usually be arranged in such a manner that the hopper cars, if the plant has a railway siding serving it, or the coal wagons, can dump their contents into the hopper of a coal crusher, the crushed coal being delivered into the bucket conveyor, and thence elevated to the overhead bunker. By partitioning off one end of the overhead coal bunker a receptacle for ashes can be made which communicates by means of a shute with the railway siding or yard. The ashpits of the boilers are arranged to slope down to a tunnel in which the lower flight of the conveyor runs. The same conveyor thus serves for both ash and coal handling.

If, by reason of getting all coal in during two or three months of the year, more favorable prices can be obtained, and there is space for yard storage, some means of unloading cars and piling the coal must be installed. Provision must also be made to reclaim coal from yard storage to bunker. For this purpose either a locomotive crane, overhead trolley carrying a grab bucket, or portable conveyors can be used. If tracks are already laid in the yard, an electric or steam locomotive crane can be usefully employed. The overhead trolley system is good if the coal can always be stored in the same position and a straight way communication with the boiler room can be obtained. For the general run of yard storage in medium sized plants the portable conveyor offers the best solution, as it can be moved around to suit conditions independent of tracks or overhead construction.

Where the amount of coal to be handled on the firing floor is over two tons per hour, it will, in general, be economical to instal mechanical means of coal handling. The amount of ashes to be handled will usually run from one-tenth to one-fifth of the amount of coal fired. It may be necessary to arrange separate ash handling machinery so that the continuous operation of the coal conveyor will not be interfered with, and a number of plants are now using the vacuum or steam jet ash conveyor for this purpose.

For handling coal over long distances such as from a ship at the wharf to yard storage, a combination of belt conveyor and drag bucket may be used to good advantage. The belt conveyor can be used over considerable distances and at fairly high speeds, and the ordinary run of coal is not particularly abrasive. It can be arranged on a rising incline from wharf to storage, and a drag bucket on a trolley arranged at right angles to the shore end of the belt conveyor can be used to spread the coal out in a flat pile.

There are different conditions to be allowed for in every plant, and the purpose of this article is merely to indicate the different types of apparatus that are available, and some of the general considerations governing their use.

The use of coal handling equipment has another advantage in that it is possible to incorporate accurate weighing devices with the machinery and thus keep a reliable check on the coal being burned. In the case of the overhead bunker arrangement, the coal is delivered from the bunker to a travelling weigh larry which automatically weighs the coal as it is delivered to the stoker hoppers, printing a weight ticket in the same manner as the ordinary track scales do. If there is no overhead bunker, a weighing device can be placed at any convenient place between the receiving and delivering end of the coal conveyor. In the estimating of coal consumption by space measurement or checking the number of barrow loads or trucks wheeled into the boiler room serious discrepancies can often arise, and we know of a case where bunker storage of about 2,000 tons was carried and during the course of five years a discrepancy of about 1,500 tons between the coal received and coal accounted for was discovered. This would probably never have come to light except for the fact that a coal shortage occurred and, for the first time in years, the storage was cleaned out. This was perhaps an extreme case, but it illustrates the possibility of error due to wilful manipulation of records or carelessness.

Tube Blowing

There should be no question in any plant, large or small, as to the benefit to be gained by using mechanical soot blowers. The old method of trying to keep the surfaces of the tubes clean by hand lance is wasteful of steam and poor in results. It is a difficult and to some extent dangerous job, and there is not one man in one thousand who will conscientiously carry it out. The rubber hose used for the lance is constantly giving out, and is expensive to replace.

The installation of a mechanical soot blower, a type of apparatus which has been brought to a high state of perfection in recent years, ensures a thoroughly satisfactory means of keeping tube surfaces in the best condition with no more effort than is required to open a small valve. The use of specially prepared metals and improvements in design has eliminated the early trouble caused by burning out, and other improvements have materially reduced the steam consumption. The upkeep is small, and the return on the investment high. So successful has this particular piece of equipment been on land that it is being introduced quite considerably into marine practice, and with equally good results. Dirty tubes on long runs used to be a source of trouble in marine work, as well as much loss of fuel. Marine engineers should be grateful for the advent of the mechanical soot blower. In the case of economizers, the steam soot blower is, in many cases, taking the place of the chain scraper with which all economizers were at one time fitted.

Boiler Room Instruments

There are a large variety of recording and indicating instruments now available for the boiler room, each of which can give invaluable service if rightly applied and intelligently used. It is lamentable but true that there are still many factory managers, and factory engineers for that matter, who are under the impression that hanging some particular instrument on the wall of the engine or boiler room will immediately result in fuel saving. Naturally, when this does not occur, the instrument and all its kind are roundly condemned. When a physician places his stethoscope on the chest of a patient he does so because the stethoscope will give him an indication of what is going on within, and not for any healing properties possessed by the instrument. It is exactly the same with the instruments used in the boiler room. They possess no mag-

ideal properties of themselves, but they do indicate how far away from, or how close to the ideal operation the plant is. It is then up to the intelligence of the man in charge to diagnose the case and apply the remedies for the particular troubles indicated.

One of the first considerations governing the installation of instruments then should be the possibility of them getting fair care and attention. That being guaranteed or assured to a reasonable extent, the next factor will be what return they are likely to give on the money invested. Obviously there could be no advantage in placing an instrument costing two or three hundred dollars into a plant which had but one boiler and one man to attend to it. While it is quite possible that a salesman might show where the investment could be justified, it is doubtful if in practice it would work out. There are, of course, cases where the instrument is necessary apart from any return it may make, such as a steam recording gauge where a fire pump and sprinkler system are installed. This gauge is just as necessary as the steam gauge on the boiler, and cannot be looked at from the economical point of view at all.

The principal instruments available to the engineer today are the recording instruments such as recording thermometers, recording steam gauges, draught gauges, CO2 recorders, recording meters for steam, water or air. It is not every plant that can afford or needs a full installation of all these instruments, but there is no plant so small that they cannot afford one of them. We leave out, of course, the extremely small plant up to 50 horse power, and those plants whose fuel is the refuse from a manufacturing process and therefore has no cost. We would say that practically every plant should have a draught gauge, even if it is merely a bent tube with a 6-inch scale attached. With this simple instrument a fireman can find by experiment just what particular condition of draught gives him the most satisfactory results, and can detect leaks in the setting of his boiler.

There are a number of very good draught gauges on the market which are inexpensive and can be fitted directly on the boiler front. These are especially useful in the plant of more than one boiler, as they form a guide to the setting of the dampers on the individual boilers, as well as the main damper. Slightly more elaborate than the differential draught gauge are those which not only indicate conditions of draught but have corresponding directions for correcting wrong conditions. For instance, a direct reading instrument can be obtained which shows at a glance the flow of air in its relation to the flow of steam, and the flue gas temperature at the same time. This type of instrument is very valuable where a fireman is working without supervision, because it gives him a ready indication as easily read as his steam gauge as to whether conditions are correct or otherwise.

CO2 instruments can be obtained either giving a record on a chart or a constant direct indication, or both. There are a number of these instruments by different makers on the market. While the permanent record is an excellent thing for checking up results and discovering wrong conditions, there is no question of the value of a direct indicator right before the fireman, be the plant large or small. In the large plant it gives the individual boiler attendant a means of checking up his operation every moment, while the accompanying recorder gives the operating head the story of the day's doings in relation to all his other records.

Recording thermometers are a very useful type of instrument and can be applied to a number of different purposes. Where a feed heater is installed a recording thermometer should also be installed to show that the heater is being operated in such a way as to always get the benefit of it. Careless operation of a feed heater can largely neutralize its usefulness and a permanent record of the temperature over the twenty-four hours gives a very effective means of keeping tab on the operators as well as showing the economy effected. A recording thermometer, showing flue and gas temperatures, if used in conjunction with a draft gauge, forms a useful pilot for operating conditions where no other instruments are available. It also shows when heating surfaces are becoming dirty, for a steady rise of flue gas temperature, with firing conditions remaining the same, is a sure indication that the heat is not being absorbed. Where it is important that rooms be kept at a steady temperature, such as kilns, or drying ovens, the recording thermometer is the only means of ascertaining whether this has been carried out or not.

Meters such as the Venturi or V notch weir type, placed on the boiler feed line, give an accurate record of the amount of water evaporated. This checked against the amount of coal fired gives a direct indication of whether the fuel is being efficiently used or not. It, of course, does not tell in what way the loss, if any, is occurring, but it inevitably points out that there is a loss. If the amount of water delivered to the boiler and the temperature at which it is delivered and the quantity of coal burnt is known, there is a direct check on the efficiency being obtained.

Steam flow meters take up the story where the feed water meter leaves off. These meters may be attached to the main steam pipe of a boiler, or the main header of a battery of boilers, and show how much steam is being delivered from each boiler, or from them all. If the amount of steam delivered is less than the amount of water delivered, then there is a leak taking place, or perhaps a number of small leaks. The meter can be attached to a branch pipe leading to a particular department, and the amount of steam used by that department accurately checked. Further, if a battery of boilers in operation is fitted with a steam meter on the steam pipe of each boiler, the share of the total work being done by each can be seen at once. This is a particularly useful feature of the steam flow meter, because it often occurs that one boiler in a battery is doing considerably more work than another, the one being worked at high efficiency and the other at low efficiency.

In a large plant where the consumption of fuel is considerable, and the power costs form a considerable item of the manufacturing cost, or in a large central station where power costs are practically the whole manufacturing costs, the fitting of suitable instruments enables a check to be kept on the conversion of the fuel heat into power at every step, from the coal car to the condenser discharge.

The coal is weighed on a track scale before it is dumped from the car to the coal handling equipment, and every pound is automatically weighed as it is delivered to the boilers. The intensity of draught, the pounds of air per pound of fuel, the flue gas temperature, the feed water temperatures at entrance to heater, discharge from heater, entrance and discharge of economizers where fitted, are all recorded. The amount of feed water delivered to the boiler, the amount of steam discharged from the main steam pipes, the temperature of the steam when superheated, the temperature of the exhaust leaving the engine or turbine, the temperature of the circulating water leaving and entering the condenser, are all available in the records. The amount of ash carried out is also recorded. In this way it is possible to strike a balance sheet, which shows on one side the amount of heat delivered to the plant as fuel, and on the other, item by item, the amount of heat turned into useful work, and the amount of heat which is inevitably lost. The purpose of all the instruments employed is to keep this loss down to the smallest possible amount, and the intelligent comparison of all the different records obtained show the operating staff exactly where the losses are taking place.

In distinction to this elaborate checking up which represents the highest practice, there is the check already mentioned which is the amount of water evaporated and the amount of coal burnt. If coal of 11,000 B.t.u. per pound is being burned, and the boiler is working at 100 pounds per sq. in. pressure, and the feed is at 100 deg. entering the boiler, then there should be an evaporation of approximately 7 lbs. of water per lb. of coal, which is an efficiency of about 70 per cent. If the evaporation is only 5 lbs. then there is clearly something wrong.

If we reckon 70 per cent. efficiency as a fair efficiency to be aimed at, that means that each ton of coal is only delivering about 70 per cent. of its pos-

(Continued on page 33)

Power Can be Obtained From Refuse

The Gas Producer Has Been Steadily Improved During Recent Years, and Provides an Efficient Means of Turning Certain Manufacturing Wastes to Beneficent Uses

By F. JOHNSTONE-TAYLOR

IT IS always adequately appreciated that small power plants can often be very economically operated by burning combustible refuse in a gas producer. In new countries, especially where wood fuel is more or less plentiful, and coal both scarce and dear, does this system of power production present special advantages. The burning of wood and similar soft fuel in boilers is a wasteful procedure at the best, the boiler furnaces have to be specially constructed, and except for quite small plants in which economical operation is unnecessary, it cannot be said to provide a satisfactory solution of the power problem. Again the steam engine in small sizes is not by any means an efficient unit, although admittedly there is much to be said for engines of the locomotive type which are specially constructed for the economical operation of small steam plants. The gas engine on the other hand has so many proven advantages for this purpose that it is unnecessary to dilate upon them here. It is not, however, so generally appreciated that the suction gas producer, so well known in connection with the use of anthracite, has been considerably improved of recent years in connection with burning wood refuse and other waste products. It is now quite an established method of power production, and one which as stated, must when fully appreciated, appeal especially to power users, and prospective power users in new countries. While wood refuse is obviously the most suitable substitute for coal, besides being likely to be the most plentiful, certain industries provide a considerable quantity of other combustible refuse, which can usually be turned to equally good account. In what is to follow, therefore, although primarily the waste wood product is referred to it should be understood that it can usually after putting the whole facts before the makers, be installed for operation on most forms of dry combustible matter. Such products as sawdust, spent tan, peat, waste, cotton seed, coffee and cocoa husks, mealie cobs, cocoanut shells, sugar cane refuse, etc., are all suitable for the purpose and the mere fact that when not so used they accumulate in such quantities as to often cause positive annoyance should be sufficient to turn the power user's attention to them as a source of possible power and consequently profit.

The Suction Producer

The principle on which the suction gas producer works is exceedingly simple. Air and steam are passed through red hot fuel and converted into inflammable gases which are used for power purposes. The mixture of air and steam is sucked by an ordinary gas engine through the furnace in the gas generator, then through "scrubbers" or cleaners where all the dust or volatile matter from the fuel such as tar is washed out with water, and then into the engine. What really happens in the generator is this:—

When air passes through red hot fuel, combustion takes place and carbon dioxide gas (CO_2) is formed. This gas is the product of complete combustion and will not burn. However, as the CO_2 continues its way through the fire it absorbs more carbon and becomes CO or carbon monoxide gas. This gas is combustible and is one of the gases that go to make up the composition of suction gas. When steam is passed through red hot fuel it is split up into two gases both of which are combustible, H or hydrogen, and CO. The nitrogen in the air N passes through the generator unchanged and is mixed with the suction gas. In practice traces of other gases such as marsh gas CH_4 are found but these depend on the kind of fuel used. Under average working conditions the composition of suction gas would be about CO_2 7.2 per cent., CO 18.6 per cent., CH_4 1.6 per cent., H 17.6 per cent., N 54.4 per cent., O .6 per cent. and the calorific value would be about 140 B. t. u. per cubic foot.

From the above a rough idea can be formed of what takes place in the generator and of the composition of the gas formed but it is quite unnecessary for the attendant to know anything about these details as the whole process is perfectly automatic.

A suction-gas plant may be divided into three parts.

1. The generator in which the gas is formed.
2. The scrubbers in which the gas is thoroughly washed to remove dust and tar, etc.
3. The gas engine in which the gas is consumed and the power developed.

The Generator

Suction gas generators are made chiefly in two types; the up-draft and the down-draft. In the former air and steam are sucked upwards through the fuel and in the latter downwards. The up-draft generator, however, is almost universally used as it gives the most economical results; the down-draft type has been developed chiefly with the idea of burning soft or bituminous fuel containing a high percentage of tar or oil, the vapours of which, when driven off by the heat of the furnace, are drawn down through the red-hot fuel where they are split up into fixed gases which help enrich the gas, whereas with the up-draft generator they would either be washed out in the scrubbers and lost or would pass on and clog up the engine. With down-draft generators it is also much easier to renew the fuel and clean out the furnace

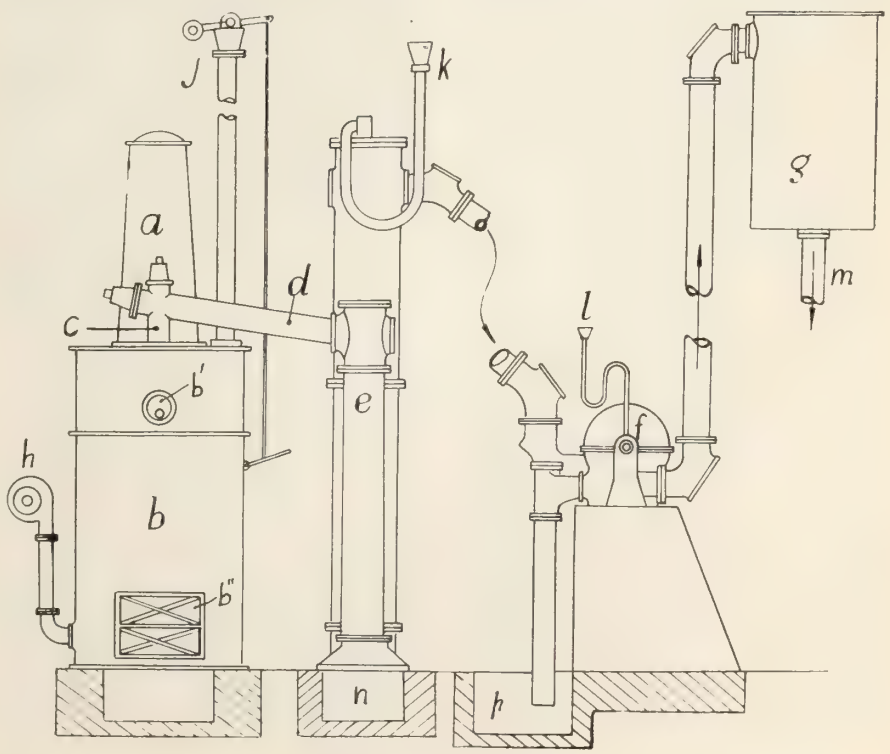


Diagram of Gas Producer.

without unduly diluting the gas with air.

Cleaning And Cooling The Gas

It was previously mentioned that a supply of steam was essential to the operation of a suction producer. Most refuse of the kind under discussion contains the necessary moisture and arrangements for supplying it are usually absent. A very important part of the apparatus, however, is the "scrubber." Scrubbers serve two purposes; to cool the gas and to clean it before it can be used in the engine. The gas leaves the generator at a very high temperature; as the volume of a gas varies with its temperature it is necessary to cool it as much as possible in order that the engine may get a full charge. Another objection to gas entering the cylinder at a high temperature is that it may cause back firing. The gas also carries with it considerable foreign matter from the furnace which would set up wear on the piston and cylinder of the engine if admitted; this is also removed in the scrubbers. The scrubber usually consist of a closed vessel in which the gas enters at the bottom and rises up against a water spray, the interior of the vessel being so arranged that the streams of gas and water are very intimately mixed. A coke scrubber is installed principally for cooling. This consists of a cylindrical iron vessel with a perforated plate a few inches from the bottom. This supports a bed of ordinary coke which reaches to within a short distance of the top of the scrubber. The pieces of coke vary in size frm 1½ inches to 2½ inches, the larger sizes being at the bottom and the smaller at the top. Above the coke is a perforated pipe or tray for distributing the water evenly over the whole area of the scrubber. The gas enters at the bottom of the scrubber and leaves at the top and in passing between the pieces of coke is broken up into very attenuated streams flowing in the opposite direction. After passing through the scrubber, which in some plants is called a dust extractor, it is usual for the gas to be treated by a tar extractor, usually of the centrifugal or rotary type, and it then finally passes through a dry scrubber which is generally a box filled with sawdust, or similar material, the actual details differing, of course, with the individual design.

The Various Types

There are several well known types of waste wood gas producer made in England, the Ruston, Crossley, and National being representative of their class. They are all adaptable to burning other forms of combustible refuse as well as wood. The general arrangement shown in Fig. 1 is that of the Ruston. Referring to the lettering on the diagram the fuel chamber is of large capacity, which is necessary to avoid too frequent charging. Before reaching the combustion zone of the generator, the fuel passes down through a distilling chamber, where, subjected to the heat of the surrounding gas it gives off volatile constituents which enrich the gas.

The generator b is constructed of thick steel plates lined with firebricks and packing, doors b2 being provided in the casing for the purpose of cleaning the fire. The firegrate consists of loose firebars which can be removed and replaced through the firedoors. It is not usual for a hopper with slide or valve to be provided for wood fuel, this being fed directly into the fuel chamber. Poking holes b1 are arranged so that any part of the furnace can be reached and the fire consolidated. Instead of leaving the generator by the usual single outlet the gas is taken off at two or more points on the top thereof by the vertical pipes c which lead into the main pipes d sloping down towards the dust collector e. The latter constitutes the scrubber. The outlets are arranged so that an even draft is ensured through the fuel bed at all points and under all conditions of load. The outlet pipes d are provided with scrapers by which tar and dust deposit can be removed at any time without interfering with production. From the top of the dust collector e the gas passes to a two stage rotary tar extractor f where the tar is thrown out before the gas passes into the sawdust scrubber. From 6 to 8 gallons of water per B. H. P. hour are required for cooling and cleaning the gas. Most of this water can be used over and over again by installing a filter, sump, and circulating pump, about 1 gallon per B.H. P. hour of clean water being required as "make up." In common with some of the other makes this producer can be used with anthracite or coke if fitted with the necessary vaporizer. The usual hand fan h is provided for starting this fire, in conjunction with the blow off valve j. Water is supplied to the dust collector e by the funnel and syphon pipe k, a similar one at l supplying water to the rotary tar extractor. The final suction to the engine is shown at m. The water seal n at the base of the dust collector enables the dust and a large portion of the tar to be deposited therein and withdrawn during the operation of the plant. The tar settling pit is shown at p. The National producer is very similar to the orthodox anthracite type built by this company. The generator operates in a similar manner to that of any ordinary producer working on anthracite or coke, and no more attention is required in the working of same. In place of the vaporizers a large cast iron dust catcher is fixed with a special water spray so that the gases are partially cleaned and cooled before passing along to the scrubbers. Any deposit which may be sucked over can easily be raked out through the water seal whilst the plant is in operation. The gas passes through a large coke scrubber for cooling purposes, and then through a rotary tar extractor which is specially designed for removing a large percentage of the impurities from the gas. Finally it passes through a dry scrubber filled with coke, wood-wool and sawdust, which ensures the gas being absolutely dry and clean before passing to the engine.

In some cases difficulty may be experienced or anticipated that the available waste product may not be sufficient to generate all the power required. This is provided for in the Crossley Wood Waste Plant owing to the fact of its being able to not only burn refuse but other forms of fuel as well, such as bituminous coal, anthracite, coke etc. In the gasification of ordinary average waste wood no steam is required, and therefore no steam vaporizer is necessary, but with anthracite, bituminous coal or coke, steam is required. It is obvious therefore that the plant suitable for gasifying any of these fuels must possess some form of steam raiser. The Crossley design is adapted to such requirements for by the simple turning of a water-tap a controllable quantity of water is admitted to the patent step fire grate and the necessary supply of steam is at once forthcoming. The result is that any mixture of fuels or an arrangement of such fuels may be used at will without complications.

The combination of fuel facilities is obtained by virtue of the Crossley Patent Step Grate and Air-lock Hopper. The use of the latter enables the power user to adapt any working depth of fuel to suit any particular requirements. The design of the hopper prevents the possibility of air being drawn in the plant when the fuel is being fed, and so removes the risk of the slowing down of the engine during the feeding of the plant. This is a most important point. This producer incorporates a Patent Step Fire Grate. Owing to its design the attendant is able to clean, poke, and maintain the fire in a constant state of efficiency with perfect ease, an accomplishment almost impossible in the older type of closed grate gas producers. The Step Grate is stated to be very efficient. The tarry matter, present in the gas as it leaves the producer, is effectively removed by a tar extractor, and may be sold or used for tarring purposes on the premises.

Fuels and Fuel Consumption

The following somewhat comprehensive list of refuse that has been at some time or another used in these producers will give some idea of their wide scope. It has been found quite feasible to produce power from:

Anthracite, sugar cane refuse, bark, bikaner coal, blocks, etc., cocoanut husks, coke, collie coal, cotton pods, safflower seed husks, shells, tea prunings, suitable non-caking bituminous coal, brown coal, crushed cotton seed, dried manure, dung cake, fruit stones, grape cake, sawdust, spent tan, wood refuse, ground nut shells, monkey nuts, jungle timber, lignite, mealie cobs, olive refuse, peat, prickly pears, rice husks, wood chippings, sunflower seed husks.

The quantities, of course, required by these various coal substitutes must be more or less a matter of speculation in the absence of definite data. Messrs. Crossley give the following figures as applicable to their plants.

Locomotive smoke-box char, 1½ to 2½ lbs. per B. H. P. hour; cocoanut shells, 1½ to 3 lbs. per B. H. P. hour; rice husks, 3 to 4 lbs. per B. H. P. hour; mealie cobs, 3½ lbs. per B.H.P. hour; olive refuse, 2 lbs. per B.H.P. hour; sugar cane refuse, 2 to 4 lbs. per B.H.P. hour.

A Large Wood Producer Plant

An example of what can be done in this direction is seen in the recent installation at Lonely Mine, Rhodesia, which was recently put down to replace a steam plant owing to the abnormal fuel consumption of the latter. There are 4 350 h.p. Crossley producers supplying 4 multi-cylinder Premier engines. The wood used is supplied in large pieces, as much as 10″ in dia. x 2 feet in length.

The engines have cylinders 17½″ dia. x 26″ stroke, 3 of these are 4 cylinder engines and one is a 3 cylinder engine. The larger ones drive A. C. generators direct and in parallel, and the smaller one an air compressor. The large engines are of 300 B.H.P. and run at 187 r.p.m. The interesting point about the plant, irrespective of its size, is the fact that it was very thoroughly tested and the results of this test throw considerable light on the subject of the waste wood producer as a whole. The makers guaranteed a consumption of dry wood fuel as follows:—

Full load .....2.0 lbs. per B.H.P. hour.
Three quar. 2.23 lbs. per B.H.P. hour.
Half load ....2.76 lbs. per B.H.P. hour.
Quarter .....3.9 lbs. per B.H.P. hour.

The actual fuel consumption at 80% of full load worked out at 2.07 lbs. per B.H.P. hour and 3.09 lbs. per K.W. hour, these being the figures for equivalent dry fuel consumption rate, and are 4% below that guaranteed. The cost of the fuel at this rate worked out at 0.20d. per unit. Interesting information was also given as regards the composition of the gas.

Calorific Values, (Gross)

These were determined by direct combustion of a known volume of the gas in presence of oxygen. The figures given represent B. Th. U. per cubic foot, at 760 millimetres pressure at 0 deg. Cent.

No. 1	148
No. 2	172
No. 3	160
No. 4	166
Average	161.5

A composite sample consisting of approximately equal proportions from each bottle was analyzed by means of a Hompels apparatus, with the following results:—

	Per cent. by volume
Carbon dioxide	1.8
Oxygen	2.5
Carbon monoxide	22.9
Hydrogen	15.4
Methane	1.0
Olefines (ethylene, acetylene, etc.)	Traces
Nitrogen (by diff.)	56.4

By calculation this gives a gross calorific value of 142 B. Th. U. per cubic foot. This figure cannot, however, be regarded as being so accurate as those obtained by direct combustion, in the Mahler calorimeter, owing to the limitation of technical methods of gas analysis in determining and differentiating small proportions of hydro-carbon gas. These results show the gas to be of high standard somewhat above the average for producer gas.

On the whole there appears to be no doubt about the efficiency of the refuse gas producer. As engineers, power users, and others become more acquainted with its obvious advantages, there is no doubt that it will replace the smaller steam plants still common in the British overseas dominions and elsewhere. Such plants can never be really economical of fuel and it must always be remembered that even if wood fuel is plentiful in any district, it cannot last an indefinite period, while pure refuse, of the various kinds mentioned, if not utilized for power production where power, and cheap power, is required, is simply so much money thrown away, a procedure which no industry with any pretence at stability can afford to tolerate.

PRACTICAL REFRIGERATING ENGINEERS' CONVENTION

In connection with the convention to be held in St. Louis, Mo., Nov. 1-2-3-4 next, we are in receipt of the following leter from the Canadian Ammonia Co., Detroit.

Gentlemen,—

Referring to recent correspondence in reference to publishing notice of the coming Convention of the National Association of Practical Refrigerating Engineers to be held in St. Louis the early part of November, it may have occurred to you the same as it did to us as to whether Canadians were eligible to attend this meeting.

We are therefore taking the liberty of quoting you from a letter just received from the National Secretary in Chicago, as follows,—

> "In reply to the inquiry in your letter of the 2nd inst., wish to say that at the Philadelphia Convention that portion of the constitution which refers to membership (Section 2, Article 6) was amended, striking out the words 'who is an American citizen,' and the section now reads,—
>
> "Section 2.—Any white refrigerating engineer who has had one or more years' experience in an ice-making and refrigerating plant and is of good moral character is eligible for membership through a subordinate association, or as a member-at-large if not subject to affiliation with a subordinate association.'
>
> "This change was made at the suggestion of the secretary last year and was made in keeping with the broad principles of the association so as not to penalize any one who might not be a citizen of the United States but who wished to perfect himself in the art and science of refrigeration engineering. The effect of this change has been felt in a small way at least, and since the last convention we have taken in seventeen new members residing in foreign countries as follows,—Canada 8, Mexico 1, Cuba 2, Australia 3, New Zealand 1, Hawaii 1, India 1. I am giving you these figures merely for the purpose of calling to your attention the wide expanse of territory in which the N.A.P.R.E. has become known."

If convenient, we would therefore appreciate your changing that part of the notice pertaining to those who are eligible to attend, to conform with the above.

Thanking you in advance, we are,
Very truly yours,
Canada Ammonia Co., Limited.

LARGE VARIETY IN APPLIANCES AVAILABLE

(Continued from page 30)

sible efficiency, and if coal is costing $5 per ton, about $1.30 is being wasted. If two tons per day are being burned, this represents a loss in 300 days of $780. It is obvious in this case that there is a case for applying some money to the purchase of instruments which will show where the loss is taking place, and enable conditions to be kept right after they are corrected. Half of this money would buy a good CO2 recorder and draft gauge which, if intelligently used, would pay for themselves in six months' use.

Conclusion

It is not within the scope of this article to go into the different classes of auxiliaries, as even to give a general outline of them would occupy far too much space. The idea is to point out to the young engineer and to the older one too, where necessary, the desirability of familiarizing himself with the different appliances now obtainable for the modern boiler room. Knowing their uses and their particular adaptability he will be in a position to advise as to what particular equipment or instrument will give the best results in the plant he is in, and show where the spending of a little money judiciously will be attended with profitable returns.

Remember that a steam plant is a manufacturing plant, and the lower the producing cost of steam is maintained the better chance he will have to share some of the profits.

Ballard Sprague and Co., Inc., of New York, have issued an illustrated booklet dealing with their specialized service in the construction of brick chimney stacks, linings for steel stacks, setting of new boilers, and general service in connection with foundations and construction work for power plants. The booklet contains a number of illustrations showing this class of work in various stages. On the last page is a table of chimney heights for different horse powers, and a table of maximum drafts with different heights of stack.

Small Steam Plant Shows High Efficiency

An Average Performance of 79 Per Cent. on a Plant of Only 800 Horsepower is Exceptional—Good Design and Attention to Heat Balance Make it Possible

FIGURES are now available showing the results of operation for six months of the Canada Paper Co.'s new boiler plant at Windsor Mills, Que., which is believed to have established a record in economy among paper mill steam plants burning coal.

The figures are particularly striking in view of the comparatively small capacity—the normal load being only some 800 boiler horsepower—while the item for fixed charges included in the cost of steam delivered compares very favorably with large modern installations.

Steam plants of less than 1,000 h.p. present the most difficult problems in balancing expenditures and returns. Features such as basements, overhead coal bunkers and extensive coal handling equipment, etc., can seldom be justified from a financial standpoint since no saving in labor is effected thereby, while instruments and auxiliary equipment represent a comparatively high proportion of the total cost and must be carefully chosen to ensure that the increased economy gained warrants the investment.

In the case of the Canada Paper Co.'s installation, further limitations were imposed by the fact that the new boiler house was built on the same site as the old plant which had been in service for over 30 years, and had to be built in sections to keep the mill in continuous operation. Actually the entire work was carried through without causing a shutdown of the mill.

The plant comprises three Goldie and McCulloch water tube boilers of the Babcock and Wilcox type, each containing 2,467 square feet of heating surface, equipped with superheaters and "Type E" stokers. Two boilers are normally in service operating at about 160 p.c. rating. Space is provided for a fourth unit.

Economizers are installed proportioned to suit the particular conditions of heat distribution and short gas passages and absence of steel flues between boilers and economizer ensures maximum utilization of all available heat in the gases.

The economizers are responsible for an increase in economy of approximately 5 p.c. under present conditions, while the superheaters are justified by eliminating condensation in the long steam pipe lines and in increasing the economy of the main engines. Changes are now being made to one of the engines to further decrease the steam consumption during the summer months so that no steam may be wasted to the atmosphere.

A coal bunker with capacity for two to three weeks' supply is arranged conveniently for filling the stoker hoppers by hand, the bunker being served by an incline conveyor from the crusher pit and track hopper, to which coal is delivered either from railway cars or from the yard storage.

Special meters are provided on the boilers to guide the firemen in obtaining maximum efficiency of combustion in the furnaces, and by means of a separate recording flow meter on the independent stream line to the auxiliaries is possible to keep a check both on the steam consumption of soot blowers, ash conveyor, etc., and also the times when they are used.

With the mill running six days per week the efficiency of steam generation in the boiler plant has been maintaind at around 79 p.c. average, including the Sunday banking, while a check run taken over seven weeks, with careful attention to weight of coal used and with periodic analysis taken of the calorific value, showed an even higher efficiency.

The following economic results are given. It will be noted that the steam and coal used per ton or pound of paper includes the heating of the mill as required during the months of March and April. For the purpose of comparing the cost of producing 1,000 pounds of steam with other plants the price and heat value of the coal must, of course, be taken into consideration. The figure of $7.50 per ton of coal is given as an average price.

Mill operation, 6 days per week.

Average daily paper production, 53.5 tons per 24 hours.

Kind of paper, news and wrapping.

Superheated steam delivered to mill per ton of paper (including heating mill as in March and April), 9.470 lbs.

Total coal used per lb. of paper (including Blr. Ho. Auxiliaries, banking over Sundays, and heating mill), .593.

Total coal heat units per lb. of paper (including ditto), 7,110 B.t.u.

Total coal heat units per 1,000 lbs. steam fr. and 212 deg., delivered to mill, 1.256,000 B.t.u.

Cost per 1.000 lbs. of steam (including coal at $7.50 per ton, 12,000 B.t.u. Labor and electric current for Blr. Ho. motors).

Superheated. d/d to mill 54.25c.

Fr. and at 212 deg. d/d to mill 45.30c.

Fr. and at 212 deg. generated 42.80c.

Fixed charges, including repairs. (15 p.c. of cost of plant), per 1,000 lbs. steam delivered to mill 10.6c

Cost per ton paper for coal (7.50 ton, 12,000 B t.u.) $4.45

For labor and elec. current in Blr. Ho. ..... .52

$4.97

For fixed charges (15 p. c. plant cost) 1.20

$6.17

The plant was designed and supervised under construction by F. A. Combe, M.E.I.C., consulting combustion and steam engineer, of Montreal, with the object of securing maximum efficiency with minimum cost.

(Mr. Combe has contributed the following explanatory notes and remarks regarding the efficiency of steam plants).

When one considers that an increase in steam plant efficiency of 10 p.c corresponds to a reduction in coal consumption of approximately 13 p.c., also that, in the case of paper mills, a saving of 10 p.c. of coal consumption represents a straight increase in net profits per ton of paper sold of from 50c to $1.00, it will be realized that the subject of economy in the steam plant is worthy of considerable attention to-day.

It is safe to say that savings of 10 p. c. to 30 p.c. in coal consumption can be made in the large majority of paper mills, especially the smaller ones, not altogether by better performance in the boiler house but, in a great measure, by a re-arrangement of the steam and heat distribution.

Statements made as to the performance of plants and mills are often misleading due to the fact that the terms used to indicate efficiency and steam costs are not clearly understood or defined, for instance.

Fuel consumption per pound paper. It is customary to mention as a factor in the efficient performance of a paper mill the "pounds coal per pound paper." Since the calorific values, i.e. the number of heat units contained in a pound—of the common grades of coal on the market to-day vary by 15 p.c. and over, a more correct indication of the efficiency is "Fuel B.T.U.'s per pound paper"; that is to say the weight of coal or fuel burned per pound of a certain grade of paper multiplied by the heat units in a pound of the fuel.

Cost of Steam Production. Similarly the cost per 1,000 lbs. of steam delivered from a boiler plant is often vaguely stated without reference or consideration to the quality of the steam produced or the temperature of water furnished to the plant. These factors may cause a variation of anywhere up to 20 p.c. in amount of coal used alone, as it will be clearly seen that more heat is required to generate steam, say, at 200 lbs. pressure and 150 deg. superheat from water at a temperature of 60 deg. than to generate steam at 100 lbs. pressure without superheat from water at 200 deg.

To compute the efficiency of steam generation and to have a common ground for comparison of steam production by boilers and boiler plants operating at

different steam pressures, degrees of superheat and supplied with water at different temperatures, it is necessary to correct all such conditions of pressures and temperatures to a single basis. This basis is taken as the equivalent amount of water at 212 deg. evaporated into steam at the same temperature, (atmospheric pressure), or, as it is commonly termed "lbs. water from and at 212 degrees."

The output efficiency of the steam plant alone is, then, indicated by the total heat units in coal supplied to the plant per 1,000 lbs. steam fr. and at 212 deg. delivered from the plant; and the economic performance is the total cost of 1,000 lbs. steam fr. and at 212 deg. delivered, including fuel, operating expenses, and fixed charges. In this way adjustment is made for the amount of steam or hot water returned from the mill to the boiler plant, which is a debit, and also for the pressure and superheat of the steam.

Efficiency vs. Economy.—Efficiency and economy are not synonymous in the matter of generation and utilization of steam. While efficiency is a measure of the percentage of heat usefully employed, economy considers the total cost of production, and the latter is, of course, the important factor from a business standpoint.

The aim in design and operation of a steam plant must be to utilize in the most efficient manner the fuel—not necessarily of the lowest price per ton—which will give the greatest production of steam for a dollar, taking into account cost of fuel, labor, auxiliary power, fixed charges and repairs on plant. In other words steam should be treated as any other manufactured commodity.

The economical utilization of steam in the mill or factory must be considered in conjunction with the boiler plant as a complete system of heat exchange and recovery. To treat them separately cannot give the best results since on such a heat balance depends the advisability of using superheated steam and, in a large degree, economizers.

It is possible to illustrate in simple diagrammatic form where all the heat units purchased as coal go to in a mill as compared with the actual requirements. Such a diagram of an existing plant generally reveals where unnecessary losses occur or where heat can be used to better advantage, not only in the boiler room but in heating, power and process systems in the mill.

No arbitrary statements can be made as to the limits in size or the type of a boiler plant to justify the installation of such features as economizers, superheaters or mechanical stokers, as each case is governed by some special conditions and by the heat balance of the system, and must be judged by itself.

The above remarks may seem obvious to many, but they are usually not sufficiently studied in the design of, or in additions made to, plants, and the resulting waste of fuel is very high. In the majority of cases this waste can be largely overcome by comparatively small expenditures intelligently made in remodelling, yielding returns of over 100 p.c.—Pulp and Paper Magazine.

MAKING TURBINES NOISELESS

H. H. Lupinski, Westinghouse Electric & Manufacturing Co.

As every engineer knows, the steam turbine is decidedly superior to the reciprocating engine for producing electric power because of its higher fuel economy, smaller size, and lower first cost. But, on the other hand, some of the first installations of turbines in hotels turned out to be very noisy, so that preference has been usually given to engines under conditions where quiet operation is essential.

The engineers of the new Hotel Ambassador at New York were not satisfied to follow this practice, however. They preferred to use the more efficient turbines, if it were possible to do so, and felt convinced that if the machines were properly installed, their slight hum could be suppressed. They, therefore, drew up specifications for a thoroughly modern plant for the Ambassador.

The equipment specified consists of three 200-horsepower non-condensing Westinghouse turbines, each of which drives a 200-kilowatt, 250-volt direct-current Westinghouse generator. Special attention was given to the turbine foundations in order to prevent the vibrations of these high-speed machines from being transmitted to the structure of the hotel. The foundations were to consist of a concrete block which was to rest on a two-inch bed of sand and was to be separated from the building's foundations by a thick layer of cork on three sides and an open space on the fourth side.

In spite of these precautions, however, the turbines could be heard in many parts of the hotel as soon as they were started up. Puzzled at this apparent failure of their plans, the engineers made a thorough examination of the installation and soon located the trouble. In pouring the concrete block, the cement had leaked out into the cork and the sand, and had formed a solid mass, thus destroying the sound-absorbing cushion that had been prepared. These defective foundations were therefore torn out and new ones laid. The rock was levelled, brought to an even surface with cement and the four sides enclosed with 8-in. brick walls up to the floor finish, the whole of which was then waterproofed. A 2-in. layer of hair felt was placed on the bed, and a 2-in. layer of compressed cork placed on top of that. Then came another layer of felt and another of cork, and this same insulation was returned up the face of the brick walls to the floor level. The interior surface was again water-proofed with 5-ply membrane felt and pitch, this returned over the top edge of the side wall insulation. Into this insulated water-proof box a concrete block was carefully poured, which extended over the side wall insulation with brass drip strip cast into the foundation.

This new arrangement solved the problem. Even in the grill room, which is directly above the turbines, not a sound from the engine room can be heard.

Another interesting feature of the Ambassador's power plant is the method used to regulate the steam supply. In order to eliminate boilers, with their smoke, dirt and trouble, steam is not made on the premises, but is obtained from the New York Steam Company. It comes in at 160 lbs. pressure, passes through the turbines, and is exhausted by them at a pressure of 7 lbs. This exhaust steam is used for heating, making hot water, operating the absorption refrigerating machinery, and for various kitchen and laundry purposes.

The largest part of the demand for steam is, of course, for heating; and if the turbines were operated with the same load all year round, a large amount of steam would necessarily be wasted during the summer months. To avoid this, a supplementary supply of electric power is obtained from the New York Edison Company.

In winter, therefore, two turbines are regularly in use (with the third as a spare), and these supply all the steam and most of the power required. In summer, however, the exhaust from one turbine furnishes all the steam needed, so the other one is shut down, and a much larger amount of electric power is drawn from the central station. A special switchboard, built by the Westinghouse Company, permits various combinations of circuits to be supplied by either the turbines or central station, in accordance with the demands for steam. In this way, the most economical ratio of purchased steam to purchased electricity can be constantly maintained.

ENGINEERS AND THE POWER EXPOSITION

(Continued from page 27)

The Exhibition is fortunate in having an Advisory Committee that understands the importance of a greater popular appreciation of the engineering problems involved in the production and use of power. The Committee is made up of Irving E. Moultrop, of the Edison Electric Illuminating Company of Boston, chairman; Dexter S. Kimball, president National Association of Stationary Engineers; Milan R. Bump, president National Electric Light Association; N. A. Carle, vice-president Public Service Production Company of New Jersey; E. B. Katte, chief engineer Electric Traction N.Y.C.R.R. Company; Fred R. Low, Editor "Power"; David Moffat Myers, consulting engineer; Calvin W. Rice, secretary The American Society of Mechanical Engineers; and the managers, Charles F. Roth and Fred W. Payne, with offices in Grand Central Palace.

The U. S. and Canadian Associations

IT IS interesting to note, that in the opinion of one of the leading power engineering journals in the United States, that the National Association of Stationary Engineers is not living up to its opportunities. The N.A.S.E. occupies the same position in the States that the C.A.S.E. occupies or should occupy in Canada. The American Association has been in existence a few years longer than the Canadian, and, of course, has a much greater membership. In an editorial comment "Power" points out that while at the recent convention of the Association, the delegates' mileage came to $29,000, and $12,000 in addition were appropriated for salaries, expenses, and committee work, the Educational Committee got only $400. While some good work has been done by the Educational Committee, in the past, it would seem that the membership as a whole has not taken the interest in education that would seem likely in a body of that kind. The commentor offers the opinion that the fault is in trying to make one particular line of educational work fit a largely diversified body of men.

This is one of the great difficulties in conducting an educational program in an association of the type of either the C.A.S.E. or the N.A.S.E. although the problem in the case of the N.A.S.E. should, we imagine, be more simple than that of the Canadian Association. In local branches which contain a large membership it is possible to split the members up into groups, and provide fitting instruction for each particular group. In locals with small membership this cannot be done, and the educational work has to be conducted for the whole membership, and this inevitably results in what many of the older members look upon as lost time as far as they are concerned. In connection with the N.A.S.E. the editorial writer in "Power" puts forth the suggestion that the Association start an educational campaign on a systematic basis, leading to a professional engineering education. This is a real constructive idea, and one that might, with benefit, be considered by the C.A.S.E. The educational program adopted at present, while good in its way, does not lead anywhere in particular, and covers such a wide field that nothing of a very intensive nature can be accomplished in any particular subject. For instance, the subject for one evening's paper is "Boilers, Furnaces and Settings." The educational work at these meetings is not started as a rule until about 9 p.m. at the earliest, and supposing that all the members remain until 10.30, which is the exception, the time is limited. It is obvious that in such a length of time only the very highest spots can be touched, and the same thing applies to the discussions. We think that the subjects of "Boilers, Furnaces and Settings" could very well have an entire session devoted to it, instead of one night.

It is interesting to know that a large, strong society like the N.A.S.E. with such a large number of men to draw from, and every opportunity to give service, seems to be having the same difficulty in its way that the C.A.S.E. has been experiencing. Both associations claim to be first and foremost educational societies, and both of them seem to have the greatest difficulty in accomplishing anything of real value along educational lines.

As far as the C.A.S.E. is concerned, an attempt is being made, but it is questionable if it is along the right lines. We think that the Grand Lodge in annual session might profitably spend a little more time on this question. During the year the officers of each branch should consider what would be the best lines to proceed along and so instruct their delegates to the annual convention.

High or Low Pressure

IN STATIONARY engineering circles, a subject that has frequently caused considerable discussion, is whether it is more economical to use low pressure steam for heating, or high pressure with a reducing valve fitted between the boiler and the heating main. In this issue we have published a very complete investigation into the matter by Mr. Edgar Buckingham, of the United States Bureau of Standards. He shows in this that while it is true that the radiation losses are higher for the same pipe surface with high pressure steam, than with low, the high pressure pipe can be made of smaller diameter to offset this. The pressure loss due to friction in the smaller pipe, does not appear as a heat loss, where the steam is to be used for heating. The heat remains in the steam, and is available when the steam is condensed to water in the heating system. If steam is to be used for power, the heat loss is required in the engine or turbine, where it is converted to work, and any heat drop in the pipe is unavailable for conversion into power.

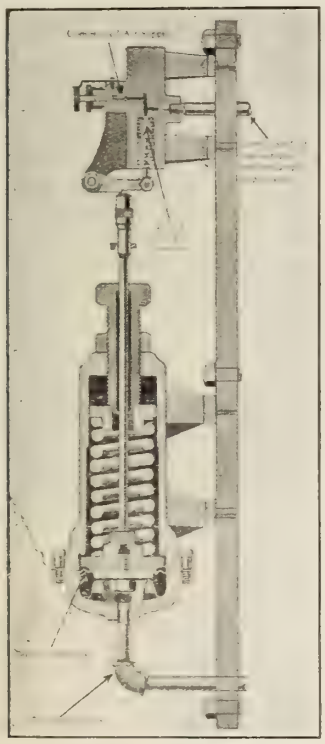
This investigation shows that in a plant that is to be used purely for heating, it may be more economical to instal high pressure boilers and piping, with reducing valves, from a point of view of saving in first cost. It also opens up the question of whether it might not be more economical, in the case of a plant using exhaust steam during the day time, and reduced live steam for nights and week ends, whether it would not be a paying proposition to instal a separate high pressure line to carry the steam to the heating coils, especially where the distance from the boiler room is great. The writer recalls a plant in which the power house was situated in the centre of the factory grounds, and the heating main was carried in a tunnel extending on each side a distance of about 100 yards to the basement of the building to be heated. These buildings were respectively 600 feet and 750 feet in length, and there were extensions besides. The heating main to the office had to run a distance of about 500 yards, with branches to other buildings taken off on the way. The main heating pipe was 24 inches diameter, and when no exhaust was available steam at 150 lbs. was reduced to 10 or 15 lbs. in the engine room, and delivered to this pipe. It was small wonder that coal consumption on a purely heating load was higher than on a power load, with exhaust used for heating.

Progress in New Equipment

THE GRAY AUTOMATIC CONTROL

The above system of automatic control is based on the principle that there is a certain over-fire vacuum, or draught intensity, which is the fundamentally correct one. At this draught there is the minimum tendency to cause influx of cold air into the furnace through the setting, and the velocity of the gases is such that the heat absorption is at a maximum. As the pressure in the furnace is below atmosphere, if only a slight amount, there is not the excessive radiation that exists with a positive pressure.

The Gray Automatic Combustion Control, manufactured by the Automatic Fuel Savings Co., Philadelphia and Chicago, is designed to keep a constant over-fire vacuum and steady steam pressure no matter what changes occur in the condition of the furnace. The regulation of fan and damper is controlled by an air pressure of 15 lbs. per sq. in.



Pressure Regulator.

through a regulator which is, in turn, actuated by the variation of pressure in the main steam pipe acting on the diaphragm. The regulator consists of a spring which is set to the required pressure to be carried on the boiler, and this

Vacuum Control.

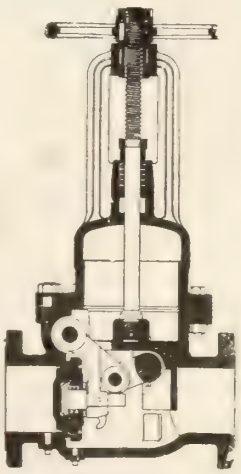
spring is opposed by a diaphragm which is exposed to the steam pressure. A spindle passing up through the spring and attached to the diaphragm carries a needle valve at its top end and this needle valve controls a port which gives access to the atmosphere. If the steam pressure drops, the spring overcomes the resistance of the diaphragm forcing it down. This opens the needle valve to the atmosphere and the compressed air which in turn is acting on diaphragms controlling the damper and fan is allowed to escape thus opening the fan and damper control.

The over-fire vacuum control is effected as follows: The furnace air controller is set for whatever over-fire draft has been determined as being the best for the fuel, and any alteration from that draft, however slight, will cause the air to act and restore normal conditions. The controller comprises an exaggerated U tube partly filled with non-evaporating oil. It is connected to the furnace chamber above the fire by means of a draft pipe. An element which floats upon the oil is fastened by an arm hinged to the side of the compressed air leak port. As the furnace draft or vacuum increases or decreases the U tube oil level is raised or lowered. This action causes the arm fastened to the float to open or close the compressed air leak port. The operation can be summarized thus: Upon a sudden demand for more steam the steam pressure controller opens the damper. The greater damper opening increases the furnace vacuum, which in turn registers on the vacuum pipe connected to the U tube of the controller. The increased vacuum raises the level of the oil on one side and lowers it on the other, carrying the float. The downward movement of the float brings the arm to rest on top of the leak port, closing the escape of air to the atmosphere. Compressed air pressure then builds up under the diaphragm operating the steam valve to individual turbo blower or wind blast gate. The blower speeds up or the blast gate opens sufficiently to build up the under-grate pressure and bring the over-fire vacuum back to the predetermined and desired point.

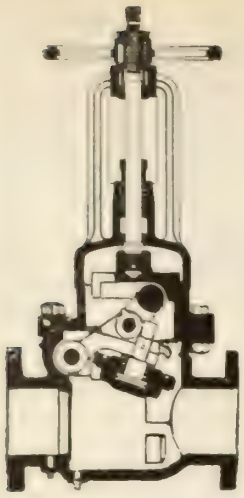
A NEW REGRINDING VALVE

The regrinding gate valve shown in the accompanying illustrations has been designed for high pressure steam and high superheat pressures up to 300 lbs. per square inch and temperatures up to 750 degrees F. have been allowed for. The body of the valve is made of cast steel, and the valve seatrings of nickel composition. The valve is made so that when it is in the open position, the opening is of the same area as the pipe itself, and for this reason there is practically no tendency to wiredraw, and the drop in pressure from this cause is practically eliminated.

Among the advantages claimed for this valve are no obstruction to steam flow, or change of direction. Higher effective working pressure can be utilised. Higher rate of steam flow is possible than with an ordinary mushroom valve, and for this reason piping of smaller size can be used, reducing the first cost of pipe installation. Loss of heat by radiation is reduced owing to smaller pipe sizes. Ease of valve operation is secured due to the special toggle lever movement. The valve disc is



View with valve closed.



View with valve open.

readily accessible for regrinding without dismounting the valve. Minimum cost of operation and upkeep is insured.

The valve seat is at right angles to the horizontal axis of the body. Closing is effected by the disc which is rigidly connected to a swing link suspended on a shaft. Attached to the swing link is a threaded disc stud which is secured to the valve disc by means of a disc nut. The disc is so designed as to insure a perfect seating of the contacting surfaces. The purpose of the spring shown is merely to prevent vibration of the disc and at the same time to give a slight flexibility of operation.

Opening and closing the valve are accomplished by means of a sliding carriage that moves at right angles to the horizontal axis of the body. This carriage slides practically without friction. It is rigidly attached to the vertical rising spindle and can be made to move up and down by turning the hand wheel.

A forked link is connected by pins with the sliding carriage and the swing link. This forked link is inclined slightly from the horizontal and forms with the slide a toggle lever that exerts pressure against both the swing link and the disc, thereby forcing the disc firmly against the valve seat.

Lugs are provided in the housing for limiting the downward movement of the slide in instances where the packing rings are especially worn either because of excessive grinding-in of the valve or for any other reason.

There is no side thrust on the rising spindle when the valve disc is being raised from the seat, because the slide is concentrically mounted in the housing with a snug fit, and furthermore because it extends around the vertical axis of the housing shows that the seat rings of the disc are well protected when the valve is open.

In order to grind in the valve seat, the bolts binding the bonnet to the housing are first removed. Then the pin connecting the forked link and the swing link is removed and all the internal parts are taken out with the exception of the swing link and the valve disc. The grinding operation is performed in the customary manner by adjusting a suitable wrench in the end of the disc stud, inserting the extension of the wrench into one of the holes provided around the circumference of the valve disc and by rotating the disc alternately clockwise and counter-clockwise, at the same time exerting pressure against the valve seat.

The valve disc in its highest position is so located that the seat rings are above the flange of the valve body when the bonnet is removed. Thus the rings are conveniently accessible and can be readily inspected whenever necessary.

The valve is made by the Schutte and Koerting Co., Philadelphia.

A HUNDRED-INCH SLIDE RULE

Every engineer is reputed to carry a slide rule and to use it a hundred times a day for every conceivable kind of calculation. The ordinary pocket slide rule is, however, not accurate except within rather wide limits; and, when a finer margin of error is desired it is necessary to employ a rule of larger dimensions. A British firm has recently brought out a slide rule in which the scale is 100 in. long and can therefore be relied upon to yield results in multiplication and division with an error of less than one in one thousand. The scale is arranged in twenty parallel lines, each about five inches long; and the whole thing is arranged so that the rule can be operated with one hand while the other holds the pen for recording results.

TEMPERATURE REGULATOR

A device for automatically controlling the temperature of electric, oil or gas furnaces has been placed on the market recently. The furnace temperature can be held within a 10 deg. F. range. The control mechanism operates automatically at 30 sec. intervals. When the furnace is operating within 8 deg. F. of the desired temperature, a white signal light is visible at the top of the board. Variation from the limited range high and low is indicated by red and green lights respectively. The mechanism operates the control switch, so that the error is corrected before it has deviated more than 10 deg. from the desired temperature. The control is claimed to be positive and automatic. The case of the instrument is made of cast iron and has a black enamel finish. It weighs approximately 27 pounds. These regulators are made by the Hoskins Mfg. Co., Detroit, Mich.

LONG-LIVED BRITISH MACHINERY

The capacity of British engineering productions to withstand many years of hard work is proverbial. British manufacturers have maintained their high standards in spite of the strong temptations of competition with inferior goods which are claimed to be just as good. In keeping up this standard these firms are maintaining a very ancient tradition. A short time ago some rolling mills in the north east of England were dismantled. These mills were established in 1691, and the old rolls and other machinery are still in existence. The water wheel employed is also still in working order. It was, as a matter of fact, used by the dismantling firm to operate the shears in cutting up the scrap ironwork derived from the works.

BOOK REVIEW

The "Union D'Electricite" has issued a book, printed in English, giving a fully detailed and illustrated description of the Gennevilliers Station in Paris. The book is edited by the Revue Industrielle, 57 Rue Pierre-Charron, Paris, and translated into English by C. M. Popp. It gives not only a description of the Gennevilliers layout but deals with the general scheme of electrical distribution in and around Paris in pre-war days, and the developments of which the Gennevilliers is a part. The book costs only $1 to any country in the Postal Union, and will be supplied to publishers or booksellers for 60 cents.

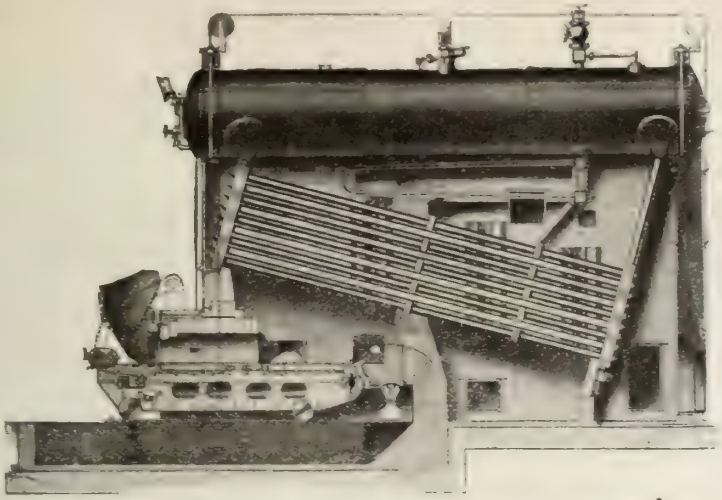
We have received a second edition of Crain's Market Data Book and Directory of Class, Trade and Technical Publications. This book gives a general review of every trade, industry and profession in the U. S. and Canada, and a list of the publications devoted to the interests of each.

CATALOGUES

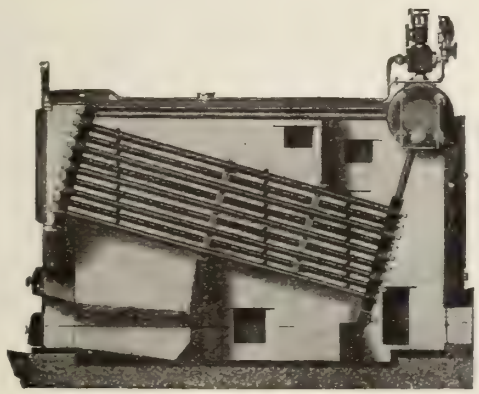
Line Shafting Equipment is the title of the latest catalogue, No. 43, issued by the Medart Co. of St. Louis, Mo. The first part of the book contains a brief description of their method of manufacturing shafting, while the remainder is devoted to the listing of a wide range of products used in transmission of every character. In addition to being a catalogue the book contains many tables and engineering data that make it very useful as a textbook.

Canadian Ingersoll Rand Co., Sherbrooke, Que., have issued bulletins K701 and K702 describing their electric, steam, and air hoists. Complete details of construction are given, and photographic views, also line drawings of the general arrangement of the different types.

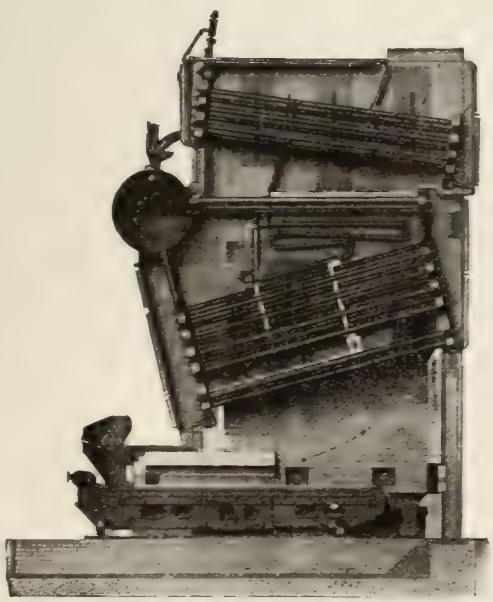
Edmonton.—Coal production in the Drumheller fields has amounted to 6,825 tons daily and will shortly be increased to between 8,000 and 9,000 tons. All the coal camps in Alberta and Eastern British Columbia are now working, and much of the product is being shipped to Saskatchewan and Manitoba. It is expected ample coal will be mined to meet all the requirements of Western Canada. The longest distance that Alberta coal has been shipped was recorded here when a local colliery forwarded a carload of egg coal to Levis, Que.



W. I. F. TYPE—With chain grate stoker and superheater suitable for most purposes on land.



CROSS-TYPE—A most desirable form of boiler where headroom is limited.



MARINE TYPE—(For land purposes). The marine-type boiler is equally adapted for installation on Land and is especially suitable for electric generating stations and other quick steaming plants. Where ground space is limited, and expensive, it offers particular advantages.

EFFICIENCY DURABILITY SAFETY

THERE IS A TYPE

OF

B. & W. BOILER

TO SUIT EVERY CONDITION ALL HAVING THE SAME PRINCIPLES OF CONSTRUCTION, VIZ:—

Water divided into sections, no general explosion can occur.

Every section able to contract and expand without interfering with any other part of boiler.

Boiler as a unit can move without disturbing setting.

Positive circulation of the water keeps all parts at nearly uniform temperature.

Proper workmanship.

Materials which experience has shown to be the best for the particular purpose.

A great excess of strength over legitimate strain.

No joints or cast metal exposed to the direct action of the fire.

Perfect circulation of both water and gases. Proper proportions for work to be done at any rating.

Ample water and steam capacity and water space for disengagement of steam.

Scale forming materials and soot can be removed while boiler is working.

All parts readily accessible for cleaning and repairs.

Adaptable to any furnace burning any fuel, solid, liquid or gaseous.

No restrictions to draft.

QUICK STEAMING.

Some Pointers on Burning Wood Fuel

Wood Fuel for Boilers Often Contains a Large Amount of Moisture—Effect of Moisture on Heat Value—Kind of Furnace Required for Burning Wood Fuel—Higher Chimney Required

By "JOHNNY SHOVEL"

OF COURSE you have noticed that people who live in the bush spend their holidays in the city. Well, we are like that. When we have our choice we take them late enough to miss the hot weather and we enjoy every minute of the time visiting around with the boys at the big power plants, making the rounds of the book stores, libraries, shows and doing everything the city man never thinks of doing.

This year we got another form of diversion. On invitation we went to the meeting of the C.A.S.E. on the night when the first subject of the yearly program was up. The general subject was Fuel and the proceedings started with a paper on Coal. We thought that there were enough good points in it for a month of discussion, but the chairman choked off the talkers and got another man started on Oil.

Even the hard working chairman couldn't prevent a certain amount of discussion while the "oil" man was on the floor, and the hour was late when at last an end was made of it to hear the man who was to talk on Wood. We are particularly interested in wood as a fuel so we listened with wide open ears to get what he said. This is what we heard and a lot of it is gospel truth.

First he remarked that it was hard to classify the methods of burning wood because nearly every place did it after a fashion of their own, and many of them with no particular method at all. But, as he had to start somewhere, he figured to talk about three classes based on the moisture which each particular sort of wood contained at the time it was fired.

Different Degrees of Moisture

In his first class he put the waste from logs taken straight from the mill pond. Such fuel would contain from 40 to 60% moisture and although the quantity of hard and soft wood might be just the same as in any other class, the arrangements for handling the waste, and the furnace would be very different and the amount of useful heat much less than from the second class, all because of the higher percentage of moisture.

In his second class he put the waste from timber which had previously been sawn to size and piled up for drying. Usually there was a lot of kiln wood in this class and the maximum moisture was not over 25%.

His third class included the fuel containing from 25% to 40% moisture.

We could imagine a great number of combinations of wood and of degrees of moisture, which would cause these classes to overlap a great deal, because one company may and often does saw, dry, plane and otherwise complete the whole series of operations required to produce the manufactured article. But the same method for figuring the useful heat would apply to all of them.

Heat Value

He showed us a table giving the heat value per pound of dry oak and six or seven other kinds oftrees and we were surprised to see that soft woods give a higher B.T.U. than hard woods. A discussion started over the reason for it and several aired opinions, but we decided for ourselves that the balsam or resin in the soft woods gives them the higher heating value.

As for that though, with the men in the woods cutting everything as it comes and the sawdust and so forth coming to the furnaces in proportions depending on the orders the mill has to get out, it is impossible to know the B.T.U. without taking continual tests with a calorimeter. For ordinary purposes all wood can be considered to have the same heat value per pound when dry and on average figure of 8,600 B.T.U. is near enough. The moisture contained is the important thing, because it determines what heat will go to make steam.

There were some who expressed wonder that wood containing 40 to 60% moisture could be useful for fuel, so the heat available was worked out on the blackboard for a sample containing 52% moisture, which means there was only 48% fuel. He took 8,600 B.T.U. as the total heat, and 48% of it leaves 4,128 B.T.U. in one pound of fuel as it goes into the furnace.

But the only means for getting rid of that 52% of water is to shove it up the stack as steam. This steam will be as hot as the stack gases, probably around 500° F., or in other words will be superheated at atmospheric pressure. Therefore, though the 48% of real fuel gives us 4,128 B.T.U., we have to use a good part of it in making steam of the other 52%.

To raise one pound of water at 62° F. to 212° F.	150 B.T.U.
To evaporate one pound of water takes (say)	970 B.T.U.
To raise one pound of steam to 500° F. ..... (Because superheat takes ½ B.T.U. to 1° F. raise in temperature).	250 B.T.U.
For one pound of water ...	1370 B.T.U.
For 52% of one pound of water	702 B.T.U.

4128—702 = The useful heat = 3462 B.T.U.

This looks small compared to soft coal at 13,000 B.T.U. per pound dry, and we should have to fire nearly 4 pounds of wood for one of coal, but if the wood costs nothing the only worry is to see that it is used economically enough so no coal will be burned.

Speaking of economy brought up the questions of cost of burning wood, and it was brought out that very few places use any large pieces of fuel. There were two reasons, first because in a modern saw mill everything of any size is marketable either as timber or for furnace and stove wood.

The only solid stuff consists of long slender pieces, known as "edgings" and thin slabs both of which are put through a machine called the "hog" and made into shreds and chips of which the largest is perhaps an inch by four inches long.

It is cheaper to "hog" this than to handle it by hand and besides both edgings and slabs are uneconomical to burn in that shape because of the excess air which would get through such an open fire. When they are burned it is usually done in a special furnace.

All the small waste from the machines is burned with the hogged fuel. Most of it is saw dust, some quite fine, some ¼-in. to ⅜-in. long, some from the shingle machine looks like excelsior. All the waste, including the hog product, is wet and too heavy to be handled from the mill to the furnaces by fan blast. Drag conveyors, endless chains pulling scrapers in troughs of wood or steel, move the fuel satisfactorily if not quite so handily as fans. It unloads by gravity through holes in the trough and chutes leading to the furnaces, the quantity being controlled by slides covering the chutes.

Kind of Furnace

The high moisture makes it necessary to burn the wood in a large, high furnace of the Dutch oven type so there will be enough brickwork to radiate the heat to evaporate the moisture and plenty of space for the gases and air to mix thoroughly. We were impressed with the fact that the steam mixed with the gases makes it more difficult for the air to get to them and mix with them and burn before they get out of the combustion chamber.

It was pretty plain from the questions asked that very few had any means for controlling the quantity of air and that some of those who had dampers on the incoming air did not require the firemen to operate them. Nothing was said

Detroit V-Type Stokers Insure Satisfied Tenants

Group of Garment Center Realty Buildings, New York, Equipped With Detroit V-type Stokers.

Tenants of public buildings demand service. They want hot water, elevator service, heat, light and power, instantly available at all times. The ability of the building management to render the service required is dependent upon efficient boiler operation. That is why Detroit V-Type Stokers are installed to-day in hundreds of public buildings.

Typical buildings equipped include:

Ellicott Square Building, Buffalo, N. Y.
Fayette National Bank Building, Lexington, Ky.
Federal Reserve Bank Building, Cleveland, Ohio
Garment Center Capitol Co., New York City
Metropolitan Bank Building, Minneapolis, Minn.
Morewood Building, Pittsburgh, Pa.
Munsey Building, Washington, D. C.
Nicholas Building, Toledo, Ohio
Pittsburgh Life Building, Pittsburgh, Pa.
Ponce-de-Leon Apartments, Atlanta, Ga.
Spitzer Building, Toledo, Ohio
Sun Life Building, Montreal, Quebec
David Whitney Building, Detroit, Michigan

Detroit V-Type Stokers are a profitable investment because with them: (a) average overall boiler efficiencies of 70-75 per cent may be maintained, (b) one man can handle up to 1200 H. P. of boilers, (c) cheaper grades of fuel can be burned than with hand firing.

On every score your boilers should be equipped with Detroit Stokers. Remember, there is a type for every purpose—V-Type Overfeed for natural draft—Single Retort Underfeed for forced draft with boilers developing up to 300-400 H. P.—Multiple Retort Underfeed for large boilers.

Ask for Bulletin 338

DETROIT STOKER COMPANY

Underfeed Forced Draft and Overfeed Natural Draft Stokers

338 GENERAL MOTORS BLDG. DETROIT, MICHIGAN

SAVE FUEL "DETROIT V TYPE STOKER" AND LABOR

about a damper regulator but we concluded that as excess air must be guarded against just as carefully as with any other fuel, it would work well.

After telling us how the fuel should be handled in the furnace, the paper gave a few details of the equipment. For one thing the stacks should be higher than for coal, because the fuel is piled up 6 or 8 inches deep on the grates even in the corners and an intense draft is necessary to get even enough air through to keep them cool. It must be larger too to enable it to handle the steam from the moisture in the fuel. He figured that to play safe it was advisable to allow only 25 to 30 sq. ft. of heating surface to one of grate surface and that one sq.ft. of grate should not be expected to develop more than 3 to 4 HPmax.

Burning the refuse from wood of the second class, say from a wood working factory, is a different matter altogether. This stuff is air dried if not better and the average usually below 25% moisture. The waste consists mostly of fine saw dust and shavings, that is chips made by the planers about ¾ in. square and anything up to ⅛ in. thick, which is readily handled to the furnaces by fans.

The useful heat is higher because less moisture is contained in the wood. It is arrived at by the same method as we used for "hogged" fuel. Probably we would only have to fire 2 to 2½ lbs. of this wood to equal one pound of 13,000 B.T.U. coal.

No special brick work is required to burn it, but a high setting gives the air the chance to mix with the gases in the steam to complete combustion.

The fuel is not allowed to pile up on the grates, in fact it mostly burns in suspension in a firebox filled with flame. Care should be taken that the furnace is not too large as it is an easy matter to waste the shavings. By studying the flame the length of it can be determined and the grates set so all flame is complete before it comes in contact with the metal of the boiler. Loose bricks can be used to get the right size of the firebox. Fill in the furnace till the grate exposed will just give you your peak load, add a bit more for safety and then brick in permanently.

The same care about excess air is necessary as with any other fuel and this class of wood refuse will give a high CO_2 if the dampers are properly maintained and operated.

All that he said about the first two classes of fuel applied to the third class. The furnace for this class would probably be of what is known as the extension type, which would give a larger grate than a flush front and some [illegible]

Glace Bay, Nova Scotia.—With all its collieries working, the output of the Dominion Coal Company's mines is rapidly approaching normal. The average output of the mines is 14,000 tons a day, and officials of the company expect to reach this figure in a short time.

PECULIAR WATER LEVEL TROUBLE

By T. Parkes,
Master Mechanic, Crabtree Mills

The following occurrence may be of interest to Power House readers, as it was the source of considerable trouble to me at the time.

We have our boilers numbered 1, 2 and 3 respectively. Nos. 1 and 3 are B & W double drum type, 300 horse power, and No. 2 is a single drum, 175 horse power.

About one year ago we experienced a great deal of trouble with No. 3 boiler owing to the difference of the height of water shown in the gauge glasses on each drum. For instance, when the boiler was operating at normal rating No. 2 drum would show 2 inches more water than No. 1 drum, and when operating at 120 per cent. rating the difference would be 5 inches. When run up to 160 per cent. rating, as frequently occurred, the water in No. 2 drum would almost disappear from the glass. Frequent internal inspections failed to reveal the source of the trouble, as the boiler was in excellent condition internally. The water we use is very soft and we do not use any compound, so we could not accuse this agent of causing the trouble. Still looking for a cause I got an idea that the dry pipe might be the guilty party, so I gave orders for the pipe to be removed. There we found the nigger in the wood pile.

The pipe was found to be broken on the top, a piece about six inches square being broken away. This would be equal to an area of about 36 square inches. What had broken it is still unknown to me, unless it was defective when first put in. We welded the piece in place again and the water trouble disappeared.

On the sketch I have marked the place where the pipe was broken and as I have previously mentioned the dry pipes are perforated on the top side, obviously the steam passage is partially restricted.

Now supposing we were operating No. 3 B & W (normal rating 300 h. p.) at, say, 150 per cent. rating or 450 B.h.p., steam 13,500 pounds per hour. The total pounds of steam would have to pass through four connecting tubes as shown in sketch, dimensions of which are 3¾ in., inside dia. 5 in. long.

Now at 140 lbs. pressure the velocity of the steam passing through the four tubes will be approximately 2,000 feet per minute.

Now if we chose to close the steam outlet of No. 1 drum, naturally the total quantity would have to pass through the two tubes of No. 2 drum, namely 13,500 lbs. We would also find that the velocity of the steam is 4,000 feet per min. instead of 2,000.

For simplicity suppose we were to remove the dry pipe from No. 2 drum which would represent conditions just as we found them.

What would probably occur?

My opinion is that we would have a combination of pressures, dynamics and statics actually taking place in the drums.

Dynamic pressure in No. 1 static in No. 2 drum.

Therefore it would seem that the load on No. 1 drum will be at rest, so to speak, and the velocity of the steam leaving No. 2 has greatly increased.

Consequently the pressure in No. 1 drum will be somewhat higher than No. 2. Whereby the pressure difference

All EDWARD Valves have the Edward Protected Seat and Disc

The Edward Protected Seat and Disc, shown above, insures absolute protection of the most vital organ of the valve anatomy, *the seating surface.*

Unless positive means of prevention is provided, the cutting from wire drawing between the seats and disc of a valve will rapidly destroy the seating surfaces. This is especially true under high pressures and temperatures, where very small leaks will rapidly grow on account of the terrific erosive action making the life of the valve very short and increasing the upkeep cost due to frequent repairs and renewals.

In the "cracked" position the erosive action of the steam is greatest, due to the fact that the steam is being wire drawn through a very small orifice and its velocity thus greatly increased. The illustrations show the positive protection which the EDWARD PROTECTED SEAT and DISC affords against this cutting action. Note that in the "cracked" position the seating surfaces are widely separated and protected from the direct flow of steam and that the velocity across the seating surfaces is greatly reduced.

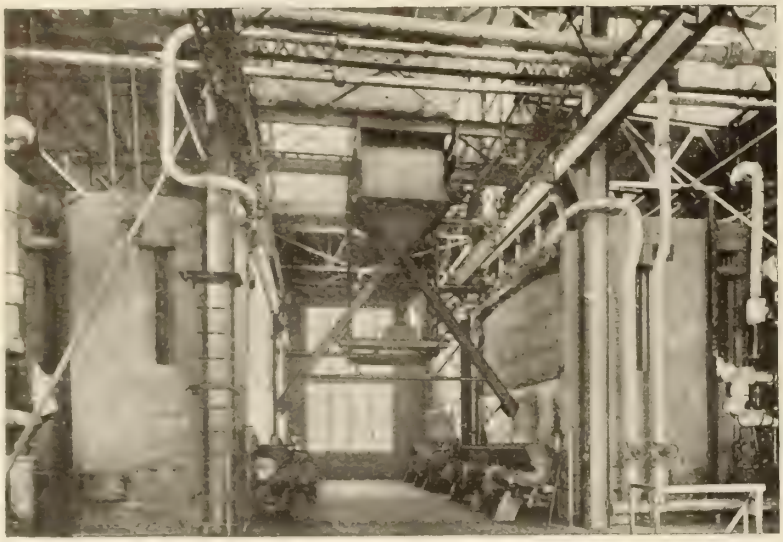
Heat Costs Money—Why Waste It?



These four 1050 h.p. boilers in the power plant of the Dominion Power & Transmission Company, Toronto, Ontario, are insulated with 45,000 Nonpareil Brick placed in the setting walls and over the steam drums.

Heat losses by conduction, radiation, etc., have for years been common to all power house plants. They have, in fact, been accepted as a sort of necessary evil.

Where comparatively high temperatures are employed the insulation material must be more than merely a good non-conductor. Fusing, shrinkage, convenience, structural strength, etc., are factors that must be considered.

NONPAREIL INSULATING BRICK

has, by actual experience, met these exacting requirements to a remarkable degree. It forms a permanent, built-in insulation; unaffected by jars, vibrations or by expansion and contraction. As for efficiency, by actual tests it has reduced by about two-thirds the heat loss by conduction and radiation. The saving in fuel alone will repay the cost of installation in a year or less.

The uses and advantages of insulation in brick form, are explained in the 72-page book, "Nonpareil Insulating Brick," which is sent free on request. Write for it.

ARMSTRONG CORK & INSULATING CO., LIMITED

503 McGill Bldg., MONTREAL 11 Brant St., TORONTO

SOME POINTERS ON BURNING WOOD FUEL

(Continued from page 40)

would cause the water to flow into No. 2 drum.

Of course the rate of flow undoubtedly will be proportioned to the boiler load.

The Effect

I may say the high water affected the plant in general causing a great deal of repairs through leaky joints, also glands on steam pumps and engines which needed constant attention.

We also noticed that when operating No. 3 boiler above normal rating our coal consumption per B. H. P. was extremely high, maximum being 4.7 lbs. per B. H. P. against No. 1 boiler operating at 70 per cent. efficiency or 36 lbs. per B. H. P.

I may go on to say in cases of this kind where engineers are troubled more or less with high and low water, especially when operating their boiler at a very high rating, it would be to their interest to examine the dry pipes thoroughly in order to determine whether or not the holes are partially plugged. Possibly the gasket may leak or the area of the pipes themselves may be somewhat different.

MORE WORK FOR HENRY WRIGHT

Mr. Henry Wright, A.M.E.I.C., chief engineer Montreal Street Railway, Hochelaga Power Plant and president of the Grand Lodge C.A.S.E., has been appointed instructor of the engineering classes at the Central Y.M.C.A., Montreal, for the season 1922-23. This, we know, will be a congenial task for the energetic Henry, who is never more happy than when helping the other fellow along.

C. A. S. E. MEMBER APPOINTED

Mr. J. H. Clarkson, St. Lambert, Montreal, has been appointed to the position of Chief Engineer of the new $8,000,000 Mount Royal Hotel, Peel Street, Montreal. Mr. Clarkson is well known in Montreal engineering circles, having been for some years chief engineer of the Central Y. M. C. A. in that city. Mr. Clarkson is an old member of the Canadian Association of Stationary Engineers and it is a pleasure to the members of his own branch in particular, and the association in general, that he should have received such an important appointment.

Waterville, N. S.—A pre-cooling plant of unique design is being installed in connection with the fruit storage warehouse by the Department of Agriculture. It consists of an ice tank with capacity of three tons, air ducts, gasoline engine and large insulated fan with capacity of 4,000 feet per minute. Air is forced through the ice tank in such a way as to ensure continuous circulation and even temperature.

BOILER INSPECTION CRITICISM

Editor, Power House,

Dear Sir:—

Does it not seem queer that in the banner province of the Dominion we have one of the poorest boiler inspection laws in the country, an act whereby anyone obtaining permission from the deputy minister in writing or holding an engineer's certificate of any class can inspect a boiler, and that inspection is accepted by the chief factory inspector.

Our western provinces have a law whereby no one without he holds a certificate as a boiler inspector can inspect a boiler, and that is the way it should be done, as it takes time to make an inspector.

Another thing, in Ontario the inspection of boilers is under two different departments, new boilers under the Boiler Inspection Department, and boilers in operation under the Factory Inspection Act.

It is about time that the engineers, in fact everyone connected with the operation of boilers, woke up to the fact that the inspection of boilers should be placed under one head so that a correct account of the boilers can be kept.

Now, Mr. Editor, I will not say any more but would like to hear what other engineers have to say.

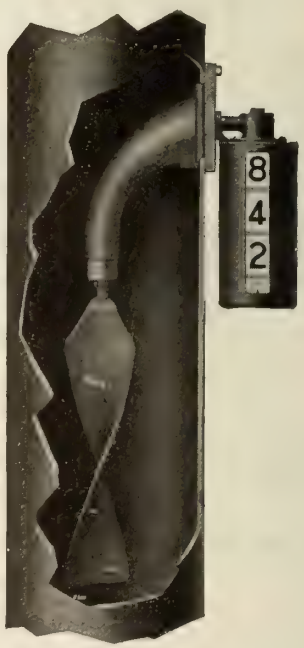
Nothing Complicated or Expensive About this Bailey Coal Meter



It is not necessary to install extremely expensive and complicated weighing apparatus above each coal chute to get the individual coal consumption of your boilers.

The Bailey Meter for Coal can be installed easily in existing coal chutes at a very moderate expense. No external power is required for its operation and, although built to withstand hard usage, it will give surprisingly accurate and consistent results with a minimum of attention.

The Vane is suspended from a ball bearing—dust proof and fully protected. The illuminated counter has figures 1½ inches high and may be read at a distance of 50 feet.

Write for Bulletin No. 220 which gives full description.

Bailey Meter Company Limited

177 Delorimier Ave., Montreal, Que.

You Know the Reputation of This Equipment

As superintendent or engineer, there can be no doubt that you have more than a "nodding" acquaintance with the products of the manufacturers listed here. Without exception they are lines that have established an International reputation for reliability—you'll appreciate that, too, from your own experience.

The popularity of these lines and the high standing of these manufacturers, whom we represent in Ontario, reflects our desire to handle only the most modern of high class Power Plant equipment.

In addition, we aim also to be of real service in coping with Canadian conditions and requirements. We maintain a staff of engineering specialists competent to advise on any unusual situation that may arise. Their service is free and without obligation.

How can we serve you?

The Safe and Certain Boiler Cleaner

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.**

BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.

Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick, and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

"There is a Tide in the Affairs of Men which Taken at the Flood leads on to Fortune"

—*Shakespeare.*

Incorporated May 1887

The better education of its members in the science of steam engineering.

—To protect the competent engineer and his vocation.

—To enroll all competent engineers in this organization.

—To impart information beneficial to the profession.

Incorporated at Ottawa June, 1917

—To assist members out of employment to obtain the same.

—To procure by legal enactment greater safety in the operation of steam plants.

—The belief that knowledge and ability of one's profession is what is necessary to make success possible.

Now is the time—not to-morrow—when you will get the most benefits from membership in the

CANADIAN ASSOCIATION OF STATIONARY ENGINEERS

IN THESE testing times the man who makes his mark is the man who devotes a large part of his leisure hours to further improvement in his chosen profession. The important part that class organizations are doing to forward this expansion can be seen when a survey is made of the large number of associations that have sprung to life in the past few years.

The underlying motive of all these associations—greater individual development—is very outstanding in the case of the CANADIAN ASSOCIATION OF STATIONARY ENGINEERS. This organization, by means of illustrated and non-illustrated lectures, provides its members with all up to the minute progress made in the engineering profession.

A GLANCE at the uper panels will show the important principles of this important organization. They are worthy of serious thought.

Any man interested in an association of this kind and living where less than fifteen engineers reside may send for a copy of our constitution and make application to the nearest lodge for membership. If living where there are more than fifteen engineers it is advisable to get together and send in a written application. The undersigned will be very pleased to give any further information required.

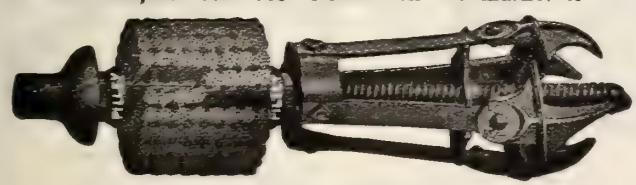
THE GARTH COMPANY
26 Craig Street - MONTREAL, CAN.

WATSON & McDANIEL CO.
No. 146 N. 7th St., PHILADELPHIA, Pa.

The Simplest and best cleaner on the market is



PILLEY'S

Combination Flue Brush and Scraper.
Guaranteed not to break or the wires to pull out or lay over. A simple turn of the hand adjusts it to the tube, and the brush removes what the scraper loosens.
For sale by leading Canadian jobbers.
Manufactured by

PILLEY PACKING AND FLUE BRUSH MFG. CO.
623 South Third Street - - - St. Louis, Mo
Eastern Office: 71 Fulton St., New York.

LADD WATER TUBE BOILERS

can be built from the smallest practical water tube unit up to 1,500 H.P. in the single type and to upward of 9,000 H.P. in the multi-drum type.

Write for descriptive catalogue.

CLASSIFIED ADVERTISEMENTS

TWO CENTS A WORD, including the "Power House" box numbers; minimum charge is $1.00 per insertion, for 50 words or less, set in 6 pt. type. Each figure counts as a word. Display ads., or ads set in border, are at the card rates.

Every Engineer, Mechanic and Electrical Worker should own this new master set. It will answer your questions.

It will help you with your daily work – A sure source of advancement and higher pay. Complete up-to-date library that is thoroughly and easily explained on every branch of modern engineering and electrical practice.

AUDEL'S ENGINEERS & MECHANICS GUIDES

4750 PAGES 8754 ILLUSTRATIONS $1 A MONTH $12 COMPLETE

These Guides tell you all about—

Theory, Practice and Operation of ALL Steam Engines; UNIFLOW and POPPET VALVE ENGINES and LOCOMOTIVE Valve Gears; Marine Engines, Turbines, Pistons, Rings, Valves, Eccentrics; PRACTICAL MANAGEMENT, Care and Operation of STEAM ENGINE rules and Formulas; Heat, Combustion, Fuel and Flue Gas Analysis; Boiler Construction of all types of Boilers; Mechanical Stokers, Setting, Chimneys, Mechanical Draught; HOW TO FIGURE A BOILER; Boiler Trials based on A.S.M.E. CODE; OPERATING HELPS; Pipes, Fittings and Valves; Refrigeration, Cooling Towers, Ice Making Apparatus, Elevators, Cranes, Ropes and Tackle. The Practical Electrical Engineer is an aid for engineers and electricians in obtaining a license—ready to answer questions covering entire field of Modern Electricity.

SHIPPED TO YOU FREE

Not a cent to pay until you see the books. No obligation to pay unless you are satisfied. Send coupon now—today and get this new master set for inspection. Pay only $1 a month.

SEND NO MONEY

THEO. AUDEL & CO., 72 Fifth Ave., N.Y.

Please submit me for approval, AUDEL'S $10,000 MASTER SET FOR ENGINEERS & MECHANICS. Ship at once prepaid, the 8 numbers. If satisfactory I agree to send you $1 within 7 days and to mail you $1 monthly until $12 is paid.

COME to the POWER SHOW

At Grand Central Palace New York City December 7-13, 1922

(Except Sunday)

The most complete exhibition of power plant equipment ever shown under one roof.

It will be held immediately following the annual December meetings of the American Society of Mechanical Engineers and of the American Society of Refrigerating Engineers and others, and will be visited by thousands of prominent engineers from all parts of the country.

See the exhibits. Talk to the representatives of the most progressive manufacturers of power plant appliances. No engineer can afford to miss this opportunity to personally inform himself on the latest developments in the power plant field.

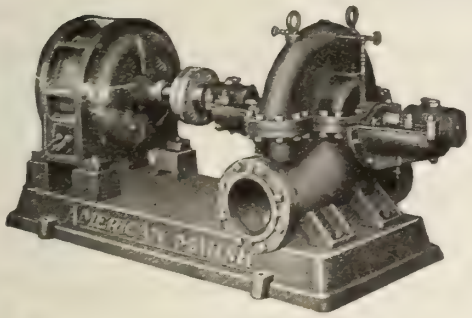
Every facility for the convenience of visitors has been provided by the management, which is the same that directed the Chemical Expositions and others during the past year.

National Exposition of Power and Mechanical Engineering

Room 1102 Grand Central Palace New York City

AMERICAN-MARSH PUMPS

Centrifugal and Direct Acting



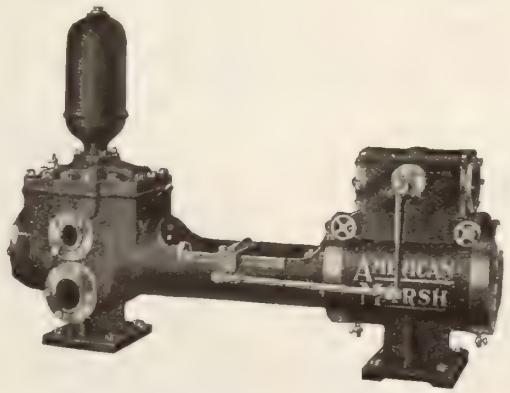
Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The Line includes :

Boiler Feed Pumps	Jet Condensers
Air Compressors	Vacuum Pumps
Deep Well Engines	Condensation Pumps
Centrifugal Pumps	Sump Pumps



May we send you our general Catalog ?

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

Get the Most Out of Your Fuel

THE BOILER D. M. LIFE SAVER

Keeps your boiler clean and thus eliminates repair bills, besides reducing maintenance cost.

Will not injure boilers or fittings.

No acid — No chemicals — Just "D. M."

"D.M." Boiler Enamel is a Vegetable composition, absolutely harmless, and will keep your boilers clean right down to the bare metal. Prevents all scale formation, corrosion and pitting. "D. M." Boiler Enamel is used by many of the largest users of steam throughout the world, including the British Government.

Manufactured by: HOUSEMAN & THOMPSON, Ltd., Newcastle-on-Tyne, England.

Sole Distributor for Canada :

J. A. CARRUTHERS - 23 Scott Street, Toronto

SMOOTH JOURNALS KEPT SMOOTH

A lining of Magnolia Anti-Friction Metal never squashes out of a properly designed bearing, yet is soft enough to let dirt and grit **sink in below the critical surface,** instead of cutting the journal in trying to push the contact surfaces apart. That this positive protection is actually present and does not appreciably diminish the anti-frictional qualities of the bearing, has been thoroughly established. Long life has characterized Magnolia anti-friction metal bearings in cement plants, brick yards, etc., where other bearing metals proved themselves to be costly luxuries.

Insist to your dealer that only Magnolia Anti-Friction Metal will be accepted and you will soon be able to see its superiority.

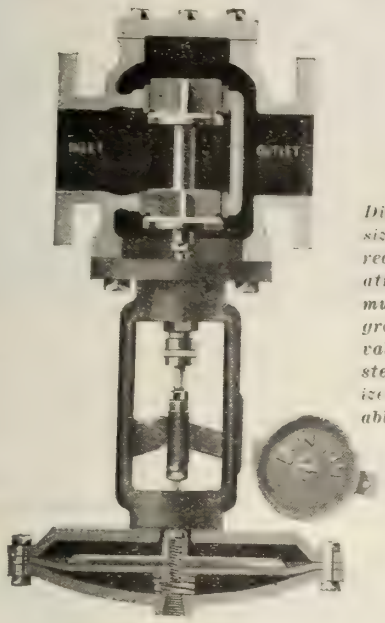
Reducing Pressure Valves
Straight Pattern — Sectional View



Diaphragms of various sizes are furnished for reduced pressures, with atmosphere as minimum. Castings of best grey iron. Seats and valves of non-corrosive steam metal. Standardized and interchangeable parts.

Steam, Water, Air Pressure Control

The Dunham Reducing Pressure Valve automatically reduces steam, water, or air from an initial high pressure to any lower delivery pressure. It affords adjustable control that secures an accurately fixed and noiseless low pressure delivery no matter how much the high pressure side of the valve might vary.

Dunham Reducing Pressure Valves are made in both Straight and Expanded Outlet types. They are scientifically designed and built of the finest selected materials to insure dependable and lasting service.

Complete data on request.

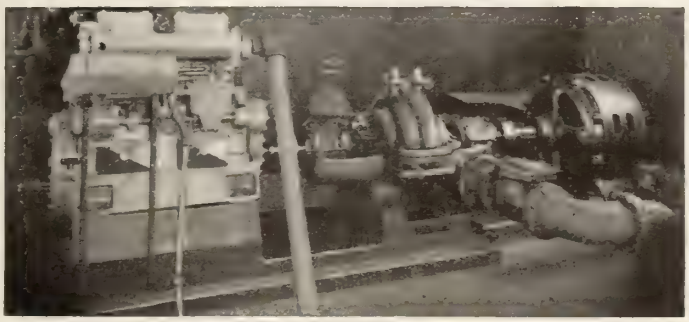
Sterling

Vs. MAXIMUM DEMAND

Analyze your power costs—it will pay you to use STERLING engines. With a STERLING engine to carry peak loads you can purchase power at the minimum rate, run your STERLING when the peak comes on, and have an efficient standby unit, ready instantly. Based on the average difference between the central station minimum power rate and the charge for demand service, a STERLING driven pump or generator set would probably pay for itself within two years.



Model GRC 4 cylinder 150 H.P. STERLING direct connected to 6″ 2 stage De Laval centrifugal delivering 1,050 G.P.M. against 260 ft. head at 1,200 R.P.M. Reserve pump installed at Seneca Falls, N.Y., by Power Equipment Co. of Boston.

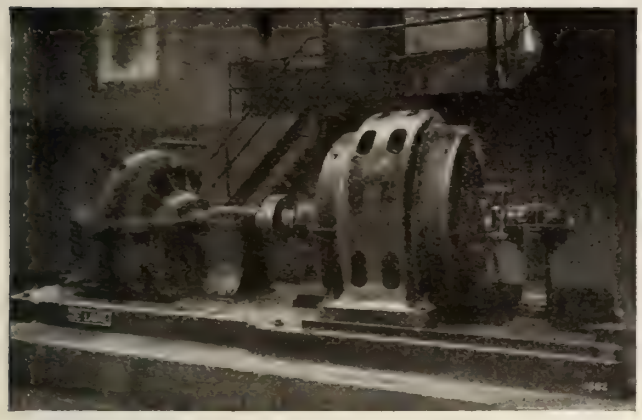
DeLaval Pump at Montreal Shows Over 86% Efficiency



TO TAKE advantage of the low cost of hydro-electric power the engineers of the City of Montreal some two years ago issued specifications for motor driven centrifugal pumps to deliver 30,000,000 Imperial gallons per 24 hours against 200 ft. total head. An official test made recently on a De Laval pump installed in 1920 gave the following results:

CAPACITY Imp. Gal. Per Day	U.S. G.M.P.	Total Head Ft.	Motor Efficiency	Pump Eff.
33,294,000	27,745	215.35	93.9	85.2
32,554,000	27,128	221.33	93.9	86.36
31,660,000	26,383	225.43	93.9	86.44
30,294,000	25,245	229.92	93.9	85.5

The high efficiency attained by this De Laval centrifugal pump is due to refinements of design developed and made possible through many years of experience in building high grade centrifugal pumps. The great amount of pioneer and continued experimental work carried on by the De Laval engineers has enabled them to determine the influence of all modifications in design and to proceed progressively to better and better results. High efficiency is also due in part to extremely accurate and high class workmanship. Accurate construction of parts and absolute interchangeability is insured by the use of limit gages in production and rigid inspection of the parts during the course of manufacture.

The continued maintenance of high efficiency by De Laval centrifugal pumps after installation is due to excellence of design and to the high grade workmanship and materials. One of the principal factors in the maintenance of high efficiency is the De Laval special labyrinth wearing ring, which prevents leakage from the discharge chamber of the pump back to the suction chamber. This type of wearing ring permits of running with greater clearances than are possible with flat rings and the life of the labyrinth ring is very much greater than of the flat ring.

All De Laval centrifugal pumps are of the horizontally split casing design, with suction and discharge connections to the lower half of the casing, so that the covers can be lifted, giving access to internal parts, without disturbing the piping connections.

Describe your pumping problems so that we may submit estimates and state the efficiencies that we are prepared to guarantee.

Ask for Catalog B100.

DE LAVAL STEAM TURBINE Co.

Turbine Equipment Co., Ltd.—73 King St. West, Toronto
The E. Laurie Co.—243 Bleury Street, Montreal, Quebec
Taylor Engineering Co., Ltd., Vancouver. 236

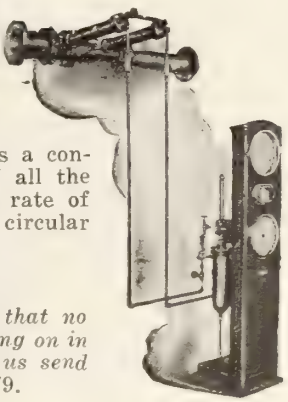
A Few Important Uses of the VENTURI STEAM METER

A close check on the steam distribution to all parts of the plant insures the speedy detection of inefficient control and preventable waste.

The Venturi may be used for measuring the steam flow to turbines, engines, compressors, heating or drying systems, evaporators, kiers, vats, cooking kettles, vulcanizers, various manufacturing processes or departments and to outside consumers.

When installed in the main boiler room header a complete record of the total steam output is always available. The relative economy of turbines and engines under different steam pressures, superheat and loads can be easily determined.

The Meter Instrument indicates the instantaneous rate of flow, registers the total flow in pounds and traces a continuous record of all the variations in the rate of flow on a 24-hour circular chart.



Venturi Steam Meter

Why not be sure that no steam waste is going on in your plant? Let us send you Bulletin No. 79.

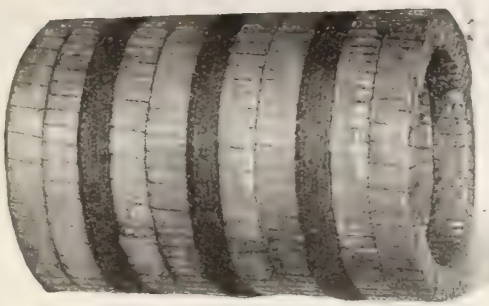
A COMPLETE SERVICE IN

"John Crane"

FLEXIBLE METALLIC PACKING



Style 104

Special Ammonia Sets

Each unit of our style 104 is a combination of cut rings from our all-metallic and channel metallic types. The metal rings seal the leakage and control the pressure, while the channels act as expansion rings.

In refrigeration service "JOHN CRANE" FLEXIBLE METALLIC PACKING has also won high honors for efficiency and durability.

Write for complete catalog. Furnish stuffing box dimensions.

Don't expect "John Crane" Results unless you use "John Crane" Packing

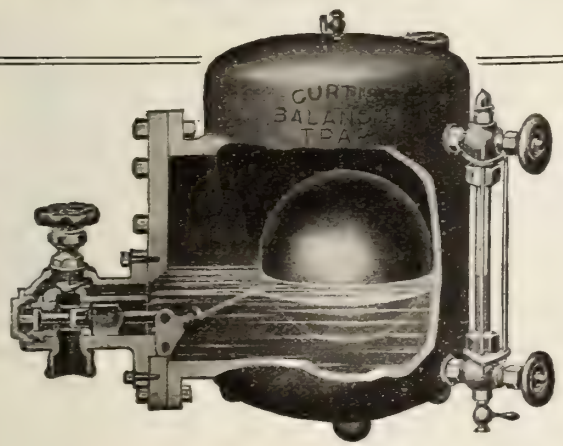
Curtis Engineering Specialties



Five Superior Features of the Curtis Trap

1. A perfectly balanced valve.
2. An absolutely frictionless valve.
3. The valve can be removed without breaking a joint, starting a gasket, or taking out a bolt.
4. The valve being frictionless and balanced, the whole power of the float is available for opening and closing the valve.
5. Each trap will operate perfectly on high and low pressures.

Write for our No. 50 Catalog of Curtis Engineering Specialties.

JULIAN D'ESTE COMPANY

Main Office, 26 Canal St., Boston, 14, Mass.

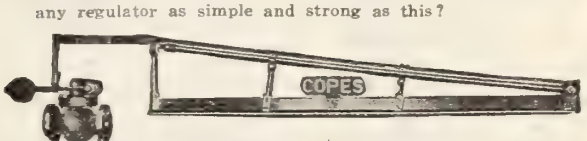
Forget—

that 98% of the Leading Central Stations use the

COPES

Boiler Feed Water Regulator

Suppose that you had never even heard of the Copes Regulator— that you knew nothing about its use in most of the world's large power plants. What would you think of any regulator as simple and strong as this?



Just a heavy thermostatic tube, and an almost frictionless balanced valve. Nothing else to it. No springs or diaphragms are used, no floats or displacement bodies. The Copes lasts indefinitely— indeed it will outlast the boiler. The inner valve parts— the only parts subject to wear— can be easily and cheaply replaced.

The rugged construction of the Copes assures you of reliability under any boiler room conditions.

Catalog D tells how the Copes increases boiler efficiency —fuel savings due to Copes regulation run from 2 to 8 per cent. This book describes the Copes method of variable water level feeding, and shows the economies that result.

WRITE FOR CATALOG D.

NO GUESS WORK HERE!

The CORY-ROYER FLOW INDICATORS have solved the problem of HOW YOU CAN SAVE in Fuel, Gas, Steam and Water Costs.

You can't keep down costs when you depend on guess work. Guess work means WASTE.

A CORY-ROYER will mean accurate checking and control of your plant efficiency.

Inexpensive—Reliable—Simple

PLIBRICO JOINTLESS

FURNACE LINING

—is the finest of refractories in the most usable form. A nine-inch lining of this plastic fire brick is easily pounded into place by any man who can use the simplest of all tools—a mallet. Then, as heat is gradually applied, it is vitrified and becomes impervious to temperatures up to 3100° F.

Jointless Plibrico conforms to every shape; it meets the requirements of furnaces of every size; it makes the ideal baffle; it is the universal lining for every type of furnace, old or new. And, above all, it is jointless!

You know that joints are wounds that never heal; that most furnace troubles start at the joints between laid up fire brick. So it follows that the cheapest furnace lining in the world is Plibrico.

Plibrico is delivered only in steel containers of distinctive appearance as shown below.

Warehouse stocks in all principal cities.

1142 CLAY ST., CHICAGO, ILL.

Better Firing with Cheaper Fuel

An emergency situation in the coal and transportation industries such as we have had, always brings forcibly to our minds the absolute need of economy and efficiency in the boiler room. Yet these needs are always there if a business is to be really successfully managed. That is why we now suggest that you write us to-day for our booklet on the National Hand Fired Stoker—which effects most important savings—is applicable to your present boilers, using any type of fuel —affords perfect stoking under all conditions—yet is an agreeably low priced installation.

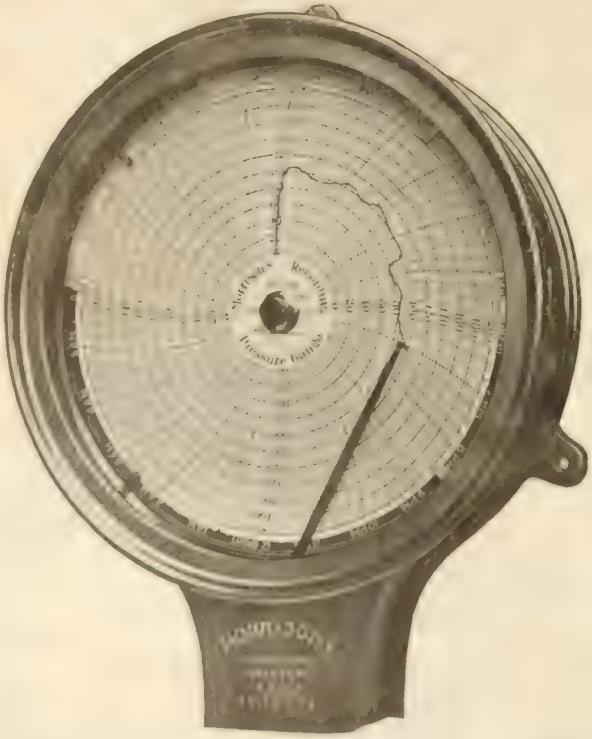
MORRISON

PRESSURE RECORDING GAUGES

Don't waste your fuel



MORRISON Pressure Recording Gauges effectively remove the worries of "trying to keep track" from the shoulders of the busy executive by giving him continuous records of steam pressure—records which tell him at a glance whether he is getting maintained pressure without unnecessary fuel loss.

Wherever installed they are considered indispensable alike to the plant executive as a simplified form of cost accounting, and to the fireman as a guidance to economical firing.

By specifying "Morrison's" you are sure of a Recording Pressure Gauge that can be depended upon for unvarying accuracy and long life under all conditions.

Sexton Says —

"I guarantee to reduce your fuel expenses by at least 10%"

WM. RUSSELL SEXTON
Member—C. A. S. E.

"Burn All"

A Child Can Operate It

There's No Better Time than the Present

It will pay you to see **"Safety First" Sexton** for all your **Firebrick Work** —building-in boilers and general repairs. Sexton has gained a reputation for doing his work with rare efficiency. His work lasts longest and many of the largest plants in Canada are ready to back up this statement.

This saving of 10% of fuel expenses isn't theory, it's an absolute fact. Some of the largest Canadian manufacturers had their experts investigate our claim and on the report of these experts they installed

NONPAREIL GRATES

They are now getting maximum heat from every pound of fuel—low grade fuel at that—because the 65% air space and 95% underdraft of NONPAREIL Shaking and Dumping Grates ensure complete combustion without waste.

You are at liberty to test the NONPAREIL under any kind of boiler for 30 days—no obligation. **There never will be a better time than the present.**

Reduce Your Power Costs With "Sirocco" Products for Mechanical Draft

Only through the use of mechanical draft and stokers is it possible to maintain the high rates of combustion necessary to carry the peak loads in modern power plants. The blower is the most important auxiliary upon which the uninterrupted and efficient operation of the boiler plant depends.

The blower, best suited for any mechanical draft installation, depends upon many factors—the kind of fuel, the boiler rating, the type of stoking, the method of drive, whether electric or steam, and numerous others. The blower is just as necessary to the power plant as lungs are to the human body.

Operating continuously, the fans must be of rugged, substantial construction.

"Sirocco" Fans are so built that dependable, never-failing service is a certainty. "Sirocco" Products afford a selection of apparatus to most efficiently meet any condition.

Our engineers will be glad to make recommendations covering your particular requirements.

Diagrammatic view of a Sturtevant Economizer Head

See Those Tapers

It is right there where the Sturtevant Fuel Economizer shows one of its many points of superiority.

Look at the illustration and you will see for yourself that the greater the pressure the tighter becomes the tube and also the header, because of the tapers.

These parts are machined so that the fit is as accurate as human skill can make it. No rust joints, no cement, no packing, just a real metal-to-metal joint.

Should repairs ever be necessary, the cap is removed, draw-out rods with wedges are inserted, and the pipe started from its tapered friction joint. A new pipe, exactly the same as the one removed, is then put in and made tight again by hammering into contact—the tapered joints,metal-to-metal fit—tight.

Send for information on Sturtevant metal-to-metal joint Economizers, installed in high-pressure power plants.

From Currying to the Finished Belt

Every Operation in the Manufacture of

D. K. McLaren's GENUINE BRITISH OAK TANNED Leather Belting

is handled by experts. Every hide used is selected with discrimination from those of the choicest steers. These are closely trimmed of all shoulders, necks and bellies and **only the tough back portions are used.** These, in turn, are subjected to the

Genuine British Oak Tanning Process

This class of tannage should not be confused with the ordinary sole leather tannage of Hemlock, commonly used by belt makers and called "Oak." The British Oak Tanning is a long-time process, not generally used because it is considered too expensive. It is to this tanning process, however, that D. K. McLaren's Leather Belting owes its reputation for that "gripping power" which means real "service on the pulley." Even under adverse conditions its remarkable stretchless quality and flexibility are an assurance of efficiency that leaves the power house engineer "worry-free."

The Oak Leaf is stamped on all D. K. McLaren's Belting as the sign of this efficiency —look for it.

Maintenance cost is low

LUNKENHEIMER REGRINDING VALVES

have proved this true by the results they have given in every class of service, extending ever a period of half a century.

The success of Lunkenheimer Regrinding Valves is determined and made certain by the Lunkenheimer method of manufacture, which provides a special bronze composition for each part, depending on the function the part performs, making the valves as near wear-proof as can be attained. Sincere workmanship together with rigid tests and inspection are further assurance of satisfactory service to the user.

The regrinding seating surfaces provide ready means for effecting repairs when necessary and at small cost.

Globe, Angle and Cross Valves and Horizontal, Angle, Vertical and Swing Check Valves for pressures up to 200 and 300 pounds.

THIS CONCRETE DAM

successfully met a severe test

CANADA is justly proud of her "white coal." The development of the Dominion's water power has employed the highest skill of the engineering profession—and in this development concrete and reinforced concrete construction have played an important part—both as regards publicly-owned and privately-owned water rights.

Our illustrations are from photos of the Southern Canada Power Company's plant at Drummondville, Quebec.

The top view shows the completed dam—and the arrow points to the location of the Power House.

The lower view illustrates the splendid resisting qualities of concrete. The breaking up of the ice nine days before the completion of the work unexpectedly flooded the dam; yet the structure was uninjured by the severe strain thus suddenly placed upon it.

You can hit it with a hammer—

Is this a foolish test?

CERTAINLY you would not test pipe covering for thermal value with a hammer.

But if a pipe covering that shows the greatest thermal value or efficiency, will also withstand the hard blows of a hammer it will surely resist the hard wear and tear frequently encountered in certain parts of the plant and factory.

Impartial tests have repeatedly shown Johns-Manville Asbesto-Sponge Felted Insulation the most efficient commercial insulation on the market. Its remarkable strength assures you that this efficiency will be maintained indefinitely.

If initial efficiency is the only quality you are interested in, the hammer test is absurd. If you are interested in the life of this efficiency and the durability of a pipe covering under severe conditions the test does tell a story.

Cold Storage Doors

Scientifically Built

The scientific construction of the Automatic Self-tightening Fastener is a notable feature of all our doors. The harder the door is slammed the tighter the fastener holds the door shut—no slackening as it fastens.

Send for Catalog No. 10—it explains in detail the numerous features which have kept **Jamison** doors in advance of all competition.

JAMISON COLD STORAGE DOOR CO.

(Formerly Jones Cold Store Co.)

HAGERSTOWN MARYLAND, U.S.A.

A shipment of Nonpareil Corkboard used in insulating the plant of the Atlantic Ice and Coal Corporation, Atlanta, Ga.

Clean-cut and Uniform

IN THE carload, as in the sample, Nonpareil Corkboard shows the high quality that has made it the standard cold storage insulation. You can depend on that quality no matter how much or how little you get.

The even color means that the boards are uniformly baked and, hence, are uniform in insulating value and structural strength. And notice the edges, how clean and straight they are. Nonpareil Corkboard does not have to be wasted by trimming out defects or crooked edges. Take them as they come; there are no "rejects" in Nonpareil Corkboard.

Clean-cut, uniform Nonpareil Corkboards can be handled more quickly and, therefore, erected at less cost than defective boards that have to be sorted and trimmed. They set up true and close and make a tight job with no "pockets" or open joints to collect moisture or frost.

Quality in a sample is one thing. Quality in the car load is quite another. You are assured of both with Nonpareil Corkboard.

Before Planning your new rooms get a copy of "Nonpareil Corkboard Insulation," a 152-page book of insulation facts that will help as well as interest you. Sent free on request with a sample.

"For Reliable Service give me YORK Equipment"

When the Operating Engineer of an Ice Making or Refrigerating Plant insists upon the Plant Manager buying York Ammonia Fittings and Supplies, he knows he is saving himself a lot of time and trouble and also reducing the operating costs of the plant.

He knows, because he has learned through past experiences of his own, or perhaps from another Engineer, that York Equipment is designed and made to meet the severest Service.

Surely, the man who is responsible for the operation of the plant, who sees and handles the equipment every day, should be best able to judge the merits of each piece of apparatus.

And the Engineer out of justice to his employers and to himself, will recommend York Apparatus, which he realizes will give satisfactory results in actual service. That's why more York Ammonia Fittings and Supplies are sold each year than any other make.

There is perhaps no other concern of its kind in the world able to handle such a large number of orders or such a heavy volume of business.

A trial order will convince you of the Superior Quality of York Ammonia Fittings and Supplies.

FRICK Combined Refrigerating Machine

This machine fills the needs of dairies, groceries, meat markets, restaurants, hospitals, confectionery and floral shops, etc., for a simple and efficient small refrigerating plant.
The machine is manufactured in one ton and two ton sizes. It is a complete self contained unit, including compressor, condenser, separator, receiver and connections mounted on one solid portable iron base as shown. It is completely assembled in one crate with motor and motor base in separate box, and can be taken through a 26-inch door without uncrating.
No foundation is required. The machine is as easily put in place as the ordinary counter or refrigerator, and as easily removed—an important feature to the user who rents his place of business.

Machine is completely protected with safety devices. Either part automatic or full automatic control is supplied as desired. It is unusually quiet in operation and can be placed in any desirable location.

Ask our nearest distributor for further details and prices.

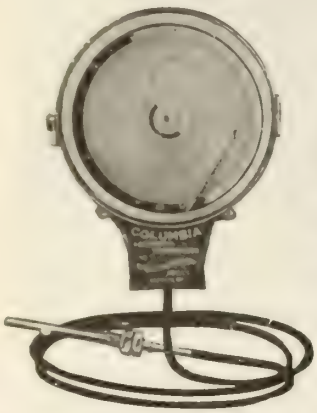
Columbia
Recording Thermometers



This advertisement is one of a series, each one of which covers one of the many "Columbia" exclusive features. In this way we believe we can best meet the inquiries we are constantly receiving for definite information.

Patent Flexible Insulating Steel Tube

The flexible steel tubing itself is the result of an engineering accomplishment of great note, the capillary bore being only one-hundredth of an inch in diameter.

A patented Insulating Covering renders the connecting tube absolutely **fume, acid and moisture-proof.** It is composed of a special waterproof insulating composition moulded around the tube and over that a layer of asbestos. This is then woven with another insulating cover and this, in turn, is carefully treated with a waterproofing compound.

An indestructible, perfectly insulated connecting tube results and yet, bear in mind, one that is flexible.

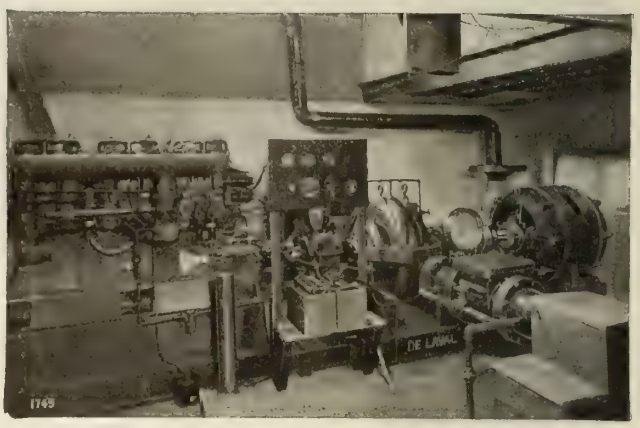
DE LAVAL
CENTRIFUGAL PUMPS COMBINE SAFETY WITH ECONOMY



THE City of Burlington, Ont., uses this De Laval two-stage centrifugal pump for both domestic and fire service.

For domestic service the pump is driven at 1160 r.p.m. by the 100 h.p. induction motor, which is supplied inexpensively with current from a hydro-electric power transmission line. Its capacity is then 900 gal. per min. against 260 ft. head.

For fire service the pump is driven at 1400 r.p.m. by the 200 h.p. gasoline engine. It will then deliver 1200 gal. per min. against 350 ft. head. For starting the gasoline engine, a storage battery with starting outfit is installed.

The low starting torque and high efficiency of De Laval centrifugal pumps particularly adapt them for both electric motor and gasoline drive. The power limiting characteristic of the De Laval pump serves to protect the motor against overload and makes it possible to select a motor developing its maximum efficiency at the normal working output. With induction motors, this makes it possible to realize both higher efficiency and higher power factor.

Our Engineering Department will gladly give you full and unbiased advice concerning the best type of pumping equipment to suit your individual conditions.

Ask for Catalog B100.

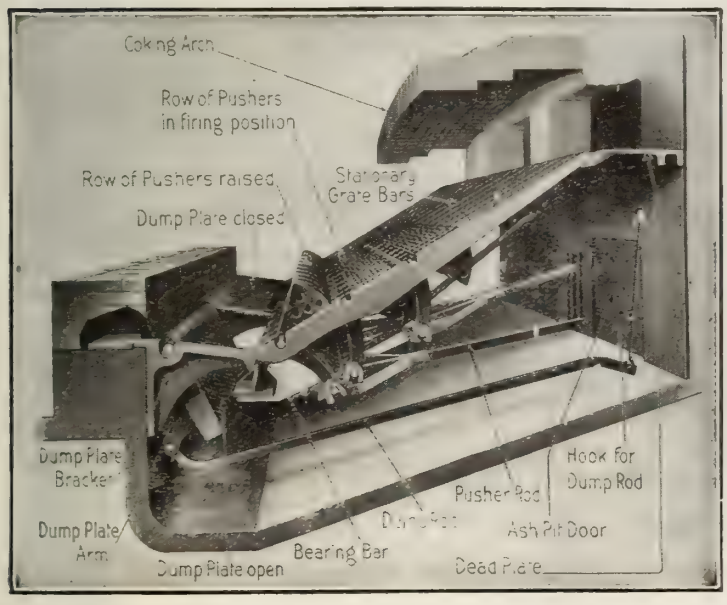
More Steam for the Upcurve!

The inflow of boiler orders coming to us shows in no uncertain way the steady mounting of the business curve. As usual, many delay ordering the new boiler they need unduly. You need more steam in your business—take thought to your boiler equipment NOW. We make boilers of every type and size to suit any duty—yet we make only one quality, the best.



The National Hand Fired Stoker Effects Big Savings

The heavy labor of firing is eliminated and low-grade labor with very little training can get excellent firing results. Any grade of fuel can be used —smoke is eliminated with all grades of coal — no fuel in the combustion chambers — no ashes in the flues — increased boiler capacity—and much lower labor cost are National advantages. The banks of Pushers, operated by rods from the front of the furnace, keep the fuel moving downward until the dump plates are reached—insuring just about PERFECT COMBUSTION.

Installed under new or present Boilers. Let us send you illustrated Booklet.

YARWAY

POWER PLANT DEVICES *to save fuel*

LARGE producers of power have almost without exception accepted the DIAMOND Valv-in-Head principle of soot blower construction as correct. They have either changed over their existing soot blower equipment to DIAMOND Valv-in-Head, or are using the new type blower in all extensions.

As with previous mechanical soot blowers, the use of the DIAMOND Valv-in-Head effects a saving of 4 per cent. to 8 per cent. fuel, and a material reduction in boiler room labor and maintenance costs.

Here the comparison ceases. Unlike any previous soot blower, the use of the DIAMOND Valv-in-Head:—

A. Eliminates condensate, thus preventing warping of blower elements.

B. Eliminates human factor, so that improper operation is practically impossible.

C. Eliminates binding of head or blower element, as a floating mechanism and ball thrust bearings are provided.

D. As compared to previous mechanical soot blowers, effects a saving of 50 per cent. in steam and labor for operation.

This brief catalogue of the advantages of the DIAMOND Valv-in-Head soot blower is incomplete. To be appreciated, the head should be seen. Ask our nearest representative to bring his working model to your office for demonstration, or arrange with him to visit some nearby plant where DIAMOND Valv-in-Head soot blowers are installed. It will be a pleasure to us to make such a demonstration. Our organization is at your service.

Principles of Levers, Pulleys, and Gear Drives

Methods of Calculation on Lever Safety Valves, Pulley Blocks, and Gear Drives Simply Explained for the Man Who Does Not Understand the Use of Algebraic Formulae

By T. H. FENNER

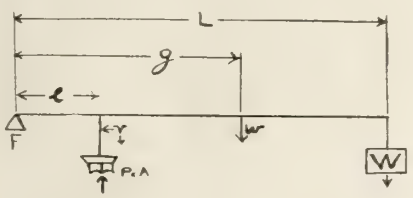
WHILE the lever safety valve is fast receding into the mists of obsolescence, there are still a number of them to be found, and in addition to this, there are numerous other applications of the lever which the engineer has to deal with from time to time. To many engineers the calculations relating to these levers present a somewhat difficult problem, especially to those who plaintively remark that they have no knowledge of algebra. While the formulae generally given are put in an algebraic form, it is quite feasible to work out any of these calculations without recourse to the mysteries of algebra, or at least without the outward forms which usually serve to define an algebraic formula. The Board of Examiners state that a candidate for a first-class certificate must be able to perform the operation of solving simple equations, and this looks formidable to a good many of the older men, and to some of the younger, but it is a fact that most of these men perform simple equations very often without knowing that they are doing so.

It is the purpose of this article to show the method of performing calculations relating to the lever, which includes blocks and pulleys, plain and differential, by what is after all only simple arithmetic such as can be used by anyone who is not familiar with the solution of formulae.

The Lever Safety Valve

Questions relating to the lever safety valve usually involve the finding of one unknown quantity, which may be either the length of the lever, the weight of the ball, the area of the valve, the weight of the valve and spindle, the distance from fulcrum to valve and spindle, or the weight of the lever itself.

Now in any form of lever there are two distinct forces, and two distinct leverages at which the forces are acting, and these forces are acting about a certain point, called the fulcrum. There is one condition that must be satisfied, and that is the force and the distance or leverage at which it acts on one side of the fulcrum, must be equal to the weight and the distance through which it moves, on the other side of the fulcrum. The weight and the force may in some cases be on the same side of the fulcrum, but the proposition holds good, that the weight multiplied by the distance from the fulcrum at which it is acting, must be exactly equal to the force, multiplied by its distance from the fulcrum. Now let us apply this statement to a lever safety valve, and first of all the formula will be given in the usual way, and the solution worked out afterwards by ordinary arithmetic and common sense. In the lever safety valve we have primarily, a set of forces acting downwards, tending to keep the valve closed, and another set of forces acting upwards, tending to force the valve open. The arrangement is such that at a previously determined pressure, the forces acting on the valve to force it up will overbalance the forces acting to keep it down, and the valve will open. The arrangement is diagrammatically as shown in the illustration.



The length L is the distance from the fulcrum at which the weight W is acting, therefore the weight XL will be the total force in foot pounds due to this combination. The distance g is the distance of the centre of gravity of the lever, or the point at which the weight of the lever itself may be said to be concentrated, and the weight of the lever itself is designated by the small w. Then the combination of wxg represents another force also acting in a downward direction.

There is still another force acting in the downward direction, and that is the force due to the weight of the valve and spindle, which is designated by v, and this weight is acting at a distance from the fulcrum of l inches. All these forces are acting in opposition to the force due to the pressure of the steam on the area of the valve, and this force is acting at a distance l from the fulcrum also. Now we may say that in general the upward forces multiplied by their leverage are equal to the downward forces multiplied by their leverage. There we have an algebraic equation, and in formula form it looks like this:—

$$(P \times A - v)l = W \times L + w \times g$$

Suppose that the problem is to find the weight of the ball at the end of the lever, all the other quantities being given. Then the formula would be this:

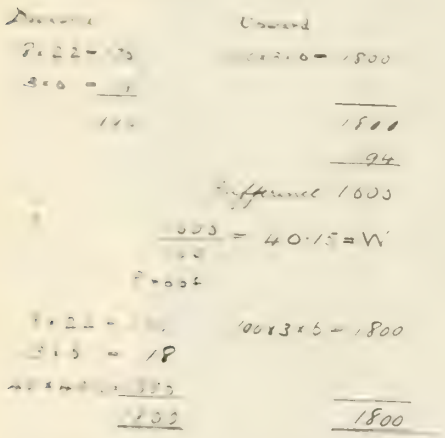
$$W = \frac{(P \times A - v)l - w \times g}{L}$$

Those unfamiliar with algebra will say at once, "How do you get that formula into that shape?" and it is a very natural question, but we are not writing this to teach algebra. Those who understand how the equation is formed will not read this article, and for those who do not, we are going to show a way of finding out the unknown quantity which will be just as good as any formula, but considerably easier to understand. This is how we will do it: First, do not forget that the forces acting down have got to be equal to the forces acting up. Now let us assign some real values to the letters we have, so that we shall have a concrete case.

Let L be 40 inches, g be 22 inches, l be 6 inches, v be 3 lbs., w be 8 lbs., pressure 100 lbs. and area of valve 3 square inches. The problem is to find W. Let us take the upward forces first. They are the pressure of the steam per square inch acting on the area of the valve, at a distance of 6 inches from the fulcrum. Putting this into figures we have
100 x 3 x 6 = 1800 ft. lb.

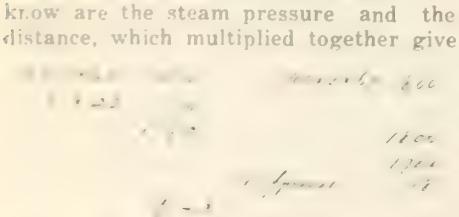
Next take the known forces acting down. These are the weight of the lever, acting at a distatnce g from the fulcrum, and the weight of the valve and spindle, acting at the distance l.

These two forces put into figures will be 8 x 22 = 176 and 3 x 6 = 18 or a total of 194. Now we have on one side a force of 1800 lbs. acting upwards. On the other hand we have a known force of 194 acting downwards, and an unknown force equal to the difference between 1800 and 194. This unknown force like the others is made up of two factors, and we know one of them. That is L the length of the lever, and we wish to know the other. Now if the force is made up of the product of W x L, and we know L and the product of the two, then it is obvious that the product divided by L will give W. Here is the simple way of stating the problem, and this method will enable any unknown quantity on the lever to be found with the minimum of trouble.



It will be easily seen that all the operations are simple arithmetic. Put down on one side of the column all the upward forces and on the other all the downward forces, in both cases this meaning known forces. They should balance. The difference between them must be the unknown force, and as you always know one factor of this force, dividing the known factor into the product gives the unknown factor. Take the problem just given, where the unknown quantity was the weight of the ball. Use this weight as just found, and all the same dimensions, but leave the weight of the valve and spindle as the unknown quantity. As we know what this should be it gives a good opportunity of checking up the work.

Take another case where the quantity not given is the area of the valve. In this case we know all the downward forces, the sum of them being 1800. Of the upward forces the two factors we know are the steam pressure and the distance, which multiplied together give



660. There is another figure to multiply by to obtain 1800, and this is obviously 1800 ÷ 66 = 3, which is the required

The foregoing should make it quite possible for the reader to see the principle. It really is the same thing as the formula in the actual working, but it makes the progressive steps towards the solution absolutely plain, and the reason for them. The same reasoning can be applied to any lever problem, always keeping in mind that the forces multiplied by their leverage which act in one direction, are exactly balanced by the forces multiplied by their leverage which act in the opposite direction.

The ordinary pulley block does not present any complication as far as the calculations are concerned. The ratios of the weight that can be lifted to the force that has to be used is a direct ratio between the number of pulley blocks or the number of parts of rope, divided into L. Thus, if we have a tackle in which there are six sheaves, and there are six parts of rope supporting the weight, then the weight will be divided equally between each part of rope, so that there will be one sixth the weight on each one. The hauling part of the rope then will require just one sixth the weight in order to effect a balance. If the weight moves one foot in height, then each part of the rope that is holding it must move one foot, and as there are six parts, the hauling rope will move six feet. Thus, if we have a weight of 600 pounds and we move it one foot in height, the product of the force by the distance is 600 ft. lbs. If the hauling part of the rope moves six feet, then the force applied must only be 100 lbs., and 100 x 6 gives 600. This is true in any combination of pulley. The velocity of the hauling rope, or the distance through which it moves, divided by the velocity of the weight is equal to twice the number of movable sheaves. In the case we have just described, there are three sheaves in the bottom block, which is the movable one. Then there are six parts of the rope, and the velocity of the moving block is one sixth the velocity of the fall, or hauling rope. On the other hand, the velocity of the weight, divided into the velocity of the rope, is one divided into six, and this gives 6, which is equal to twice the number of moving sheaves.

Another form of block and tackle is the familiar differential block, such as the Weston and others of that kind, usually known as chain blocks. Here the relation of the force to the weight is proportional to the radii of the pulleys and the gearing between them, but the exact relation of force and weight comes back to the relation of the velocity of each.

Gearing and Pulley Drives

The calculation for a train of gears or a number of pulleys can be solved very simply. The rule is to multiply all the drivers together, and all the followers, and then divide the product of all the followers into that of all the drivers. Thus if we have a shaft carrying a gear of 48 teeth, which in turn drives one of 60 teeth, and this again drives one of 90 teeth, the first shaft running at 100 revolutions, the question is to find the speed of the last shaft. The driving gears are 48 and 60, and the following gears are 60 and 90. Then

$$\frac{48 \times 60}{60 \times 90} \times 100 = 55.33 \text{ revolutions}$$

Take another case, such as in a compound winch. We have on the first shaft a gear of 24 teeth, and on the next shaft a gear of 96 teeth. On this second shaft is a third gear of 12 teeth, which meshes into gear of 24 teeth. Then the drivers are 24 and 12, and the followers 96 and 24. The speed of the last shaft is

$$\frac{24 \times 12}{96 \times 24} = \frac{1}{8}$$

or one-eighth the speed of the first shaft. If there is a line shaft running at 240 revolutions, driving a counter shaft running at 200, from which a machine running at 500 revs. has to be driven, and you are required to fit suitable pulleys, then the speed of the second shaft is $\frac{200}{240} = \frac{5}{6}$ of the first, and the machine speed is $\frac{500}{200} = 2\frac{1}{2}$ times the speed of the second shaft.

Then the pulley on the counter shaft must be $\frac{6}{5}$ or 1-1/5 times the diameter of the pulley on the main, and the pulley on the machine must be $\frac{2}{5}$ of the pulley on the counter shaft. Suppose the main shaft pulley is 10 inches diameter, then the counter shaft pulley must be $10 \times \frac{6}{5} = 12$ inches, and the machine pulley is $12 \times \frac{24}{5} = 4\text{-}4/5''$. This is not a standard size of pulley. Suppose we have a 6 inch pulley handy, for the machine. Then the countershaft pulley can be $6 \times \frac{5}{2} = 15$ inches. Then the main pulley must be $15 \times \frac{6}{5} = 18$ inches.

If no suitable pulleys can be found for one reduction then we could use a 10 on the main, driving to a 12 inch on the counter. Then from the counter to the machine we could use another pair of pulleys, say a 20 inch on the counter and $20 \times \frac{2}{5} = 8$ inch on the machine.

The speed of shafts driven by pulleys or gears is in direct proportion to the diameters of the pulleys or gears, and should present no difficulties to any man who understands multiplication and division. In spite of this, it has often come within the writer's notice that men who have pulley drives to arrange have considerable trouble in picking out the size they require for the speed.

High or Low Pressure for Steam Heater

This Most Interesting Question Has Been Treated Very Thoroughly by the Author, and His Conclusions May Occasion Some Surprise to Many of Our Readers

By EDGAR BUCKINGHAM, Physicist, U.S. Bureau of Standards, Member Am. Soc. M.E.

A LETTER recently referred to the writer contained the following requests for information: "We should be pleased to have such advice and references as to permit of our estimating the economy in steam production on a large scale which would be occasioned by generating and delivering steam for vulcanizing at 45 lb. per sq. in. as compared with generating at 190 lb. per sq. in. and delivering at the lower pressure mentioned by throttling through a reducing valve." "Would not a steam engine or turbine, for example, functioning as a reducing valve between 190 and 45 lb. per sq. in. deliver a considerable power output without appreciably reducing the heat-supplying power of the low-pressure steam as compared with the ordinary reducing valve?" "When steam is used for purely heat-supplying purposes, does the use of a reducing valve over a considerable pressure range involve any real efficiency loss, or does the superheat due to throttling bring the available energy back to its original status?"

The engineer to whom the reply was sent wrote: "The conclusions you have reached are indeed surprising, and I trust that you will find the opportunity to prepare them for publication." Without knowing whether the conclusions in question are really novel, the writer submits the substance of his reply in the hope that if these deductions from very elementary principles are known by experiment to be incorrect, the facts may be brought out, for the public benefit, by someone who knows what the facts are.

The Nature of the Throttling Process

The throttling process does not in itself cause any change in the "total heat" of the steam; and if the steam is to be used solely for heating purposes, i.e., only as a carrier for heat, the use of a reducing valve has no direct effect on the economy of the process, although there may, of course, be indirect effects on boiler efficiency and line losses, caused by the difference between generation and transmission at high pressure and at low.

The simplest way to look at the matter is as follows: We start with water at 45 lb. per sq. in. gauge (60 lb. per sq. in. abs.) and the corresponding boiling point which is 292.7 deg. Fahr. We put heat into this water in the boiler; convert it into steam at any pressure we please above 45 lb. per sq. in.; run it through a transmission line to a different place; condense it to water at the original temperature and pressure; and finally feed it back into the boiler.

During this process, aside from the insignificant work of the boiler-feed pump, no outside work is done either on or by the steam. Frictional work against the line resistance is merely dissipated into heat which stays in the steam, and does not count as outside work. A sudden large drop through a reducing valve is precisely equivalent to a great amount of line resistance concentrated in a short length of line. No outside work is done, and the kinetic energy generated at the valve is dissipated into heat which stays in the steam and dries or superheats it.

Since, therefore, the steam, in going round its closed cycle and returning to its original state of water at 45 lb. per sq. in. gauge and 292.7 deg. Fahr., does no outside work and has none done on it, the total amount of heat put into it must also be zero; otherwise the steam could not return to its initial state.

It follows that the heat put into the water in the boiler (plus the small heat equivalent of the work of the feed pump) is equal to the sum of the heat loss to the outside and the heat given up in the condenser—in this case the vulcanizer. This remains true no matter what the upper pressure may be, so that the economic questions to be considered in deciding on what pressure to use, relate to boiler efficiency, heat losses, and overhead.

If the steam is generated at an unnecessarily high pressure, which requires reduction before the steam is admitted to the vulcanizer, the reducing valve may be replaced by a steam engine or turbine. This will give a certain amount of outside work and the heat remaining in its exhaust to be given up in the vulcanizer, will be correspondingly diminished. If the bearing losses of the motor all stayed in the steam, the reduction in the heating value of the steam by its passage through the motor would be exactly the heat equivalent of the work delivered by the motor outside the bearings. Bearing losses which do not go back into the steam as reheat are equivalent to so much heat lost to the outside. They are to be added into the heat loss from the motor, which is itself merely one element of the heat loss from the whole system.

Calculations Dealing With Throttling In The Line

To illustrate quantitatively, we will suppose that the vulcanizer requires 1,000,000 B. t. u. per hour, which are to be given up by steam at 45 lb. per sq. in. gauge condensing at its saturation temperature of 292.7 deg. Fahr. We shall consider three cases: (a) generation and transmission at 45 lb. per sq. in. gauge; (b) generation and transmission at 190 lb. per sq. in. gauge, with throttling to 45 lb. per sq in.; (c) the same as (b) with the substitution of a reciprocating engine or turbine for the reducing valve. We shall suppose, in each case, that the boiler furnishes dry saturated steam, and we shall neglect pressure drop in the transmission line, and heat losses to the outside. Numerical data on steam are from the Marks and Davis tables.

In case (a), dry steam at 45 lb. (60 lb per sq. in. abs.) arrives at the vulcanizer. Its latent heat is 914.9 B. t. u. per lb., so that the amount of steam needed is—

$Ma = 10^6/914.9 = 1093$ lb. per hour.

The furnace has, in any case, to supply to the water the whole 10^6 B. t. u. per hour plus the outside heat loss. The work of the feed pump would be zero if there were no line drop, and is insignificant in any event.

Turning to case (b), the total heat of water at 45 lb. per sq. in. gauge and its saturation temperature 292.7 deg. Fahr. is $H_0 = 262.1$ B. t. u. per lb. The total heat of dry saturated steam at 190 lb. per sq. in. gauge and 384 deg. Fahr. is $H_1 = 1198.5$. The heat supplied in the boiler is therefore $H_1 - H_0 = 936.4$ B. t. u. per lb. This difference consists of 95 B. t. u. per lb. needed to heat the water from 292.7 deg. to 384 deg., and 841.4 B. t. u. per lb. which is the latent heat of evaporation at 190 lb. per sq. in. gauge. If there are no heat losses, the 936.4 B. t. u. per lb. are available for heating the vulcanizer, so that the amount of steam needed is—

$Mb = 10^6/936.4 = 1068$ lb. per hour.

When the dry saturated steam at 190 lb. is throttled to 45 lb. its temperature falls to 334.7 deg., but its superheated 42 deg. Before beginning to condense, it must cool to 292.7 deg., and in so doing it gives up 936.4 — 914.9 = 21.5 B. t. u. per lb. in addition to the 914.9 which it will give up as latent heat of condensation. To put it in another way, the dry steam at 190 lb. carries $936.4/914.9 = 1.024$ times as much heat available for extraction at 45 lb. as does dry steam at 45 lb.; so that the amount needed is only $1093/1.024 = 1068$ lbs. per hour.

In case (c), if the dry saturated steam at 190 lb. per sq. in. gauge were to ex-

pand isentropically to 45 lb. its total heat would fall from 1198.5 to 1102.1 and the difference, or 96.4 B. t. u. per lb., is the "available heat drop" which could be turned into outside work by an ideally perfect motor. The dryness factor of the steam after this expansion through a perfect engine would be 0.918; and the heat remaining available upon condensing to water would be $0.918 \times 914.9 = 840.0$ B. t. u. per lb. which added to the 96.4 makes up the 936.4 originally available.

Supposing that the motor extracts, say, 0.6 of the maximum possible—corresponding to 60 per cent. indicated efficiency in the case of a reciprocating motor—the heat drop of the steam in passing through the motor will be $0.6 \times 96.4 = 57.8$ B. t. u. per lb., so that the total heat of the exhaust is $1198.5 - 57.8 = 1140.7$ B. t. u. per lb. And since the total heat of water at 45 lb. is 262.1, the heat available in the exhaust for use in the vulcanizer is $1140.7 - 262.1 = 878.6$ B. t. u. per lb., the dryness factor of the exhaust being $878.6\ 914.9 = 0.960$.

The amount of steam needed in this case would be, for a motor of 60 per cent. indicated efficiency,

$Mc = 10^6/878.6 = 1138$ lb. per hour

as compared with $Mb = 1068$ when a reducing valve was used. The indicated power of the motor would be $1138 \times 57.8\ 2543 = 25.9$ h. p.

The pump work needed to put the condensate at 45 lb. back into the boiler at 190 lb. is less than 0.5 B. t. u. per lb., so that we have been justified in ignoring it.

Pressure Drop and Heat Loss in the Transmission Line

We may now turn to the question of pressure drop and heat loss in the transmission line, and we shall assume that no motor is to be used so that we have only to compare generation and transmission at a trifle above 45 lb. per sq. in. gauge, with generation and transmission at 190 lb. followed by throttling to 45 lb. Leaving aside the question of capital charges, we shall consider only the heat losses per foot length of the transmission line, assuming that the different lines are all equally well insulated. We may say, as an approximate rule for practical purposes, that the heat loss per foot of pipe in B. t. u. per hour will be proportional to the diameter of the pipe and to the difference between the steam temperature and the temperature of the surroundings.

From this rule it is evident that increasing the pressure (and temperature) of the steam in the line increases the heat loss from a line of given size. But if the high-pressure line can be made small enough the reduction in surface will more than offset the increase of temperature difference, so that the [illegible] be less at the high pressure. The question, then, is whether the high-pressure line can be made small

We here come to an essential difference between heating lines and power lines. In designing a power line the pressure drop along the line, which is merely distributed throttling, must be kept low because throttling diminishes the available heat drop that remains for the motor to work on. But in a high-pressure heating line followed by a reducing valve this limitation on the design is absent; for, aside from the heat losses, it makes no difference at all whether the necessary throttling takes place at a reducing valve or is distributed along the transmission line as line drop. The line drop may therefore be made large, leaving only enough drop at the reducing valve to take care of overload.

This plan seems to present several advantages. In the first place, the line can be made small and its surface reduced. Then the wire drawing in the line tends to dry or superheat the steam, which, of itself, reduces the ease of transmission of heat from the steam to the pipe. Moreover, the wire drawing, while it superheats the steam, reduces its temperature and so again decreases the heat loss. It appears, therefore, that a high-pressure heating line should be designed on entirely different principles from a power line. The line should be as small in diameter as practicable, the limit being set either by the necessity of having some drop remaining at the reducing valve, or, more probably, by the erosion of the line, which may become troublesome when the steam speed is run up very high.

Illustrative Computations of Pressure Drop and Heat Loss

It may be worth while to make some sample computations to illustrate the foregoing. Let D equal the inside diameter of the pipe in ft., S the linear speed of the steam in ft. per sec., M the mass flow in lb. per hour, and v the specific volume of the steam in cu. ft. per lb. Then we have—

$$M = \frac{3600 \times .7854\ D^2S}{v}$$

$$= 2827\ \frac{D^2S}{v}\ \text{lb. per hour} \quad \ldots\ldots [1]$$

Whence—

$$S = (Mv/2827D^2)\ \text{ft. per sec} \quad \ldots\ldots [2]$$

Let P be the pressure drop per foot length of the line. Then since the steam speed is to be high so that the resistance is nearly proportional to the square of the speed, we have, approximately,

$$P = \text{const.} \times S^2/Dv \quad \ldots\ldots [3]$$

where the value of the constant depends on the roughness of the pipe line as well as on the unit used for P. Eliminating S we have—

$$P = \text{const.} \times M^2v/D^5 \quad \ldots\ldots [4]$$

whence—

$$D = \text{const.} \times (M^2v/P)^{1/5} \quad \ldots\ldots [5]$$

To use this equation for designing purposes we should have to take a value of the constant from known experimental results; but for our present purpose of comparing different sets of conditions we only need to assume that it is the same for the different lines compared; i.e., that the lines are similarly rough. If the subscripts 1 and 2 refer to the two sets of conditions, we then have for the ratio of the pipe diameters—

$$\frac{D_1}{D_2} = \left\{\left(\frac{M_1}{M_2}\right)^2 \times \frac{v_1}{v_2} \times \frac{P_2}{P_1}\right\}^{1/5} \quad \ldots\ldots [6]$$

an equation which we proceed to apply to numerical examples.

Let our two sets of conditions be: transmission at 45 lb. per sq. in. gauge; and transmission at 190 lb. followed by throttling to 45 lb. We have already found in an earlier paragraph that $M_{45}/M_{190} = 1093/1068$; and from the steam tables we find that $v_{45}/v_{190} = 7.17/2.237$. Substituting these values in Equation [6] we have—

$$\frac{D_{45}}{D_{190}} = \left\{1.26 \frac{P_{190}}{P_{45}}\right\}^{1/5} \quad \ldots\ldots [7]$$

Equation [7] tells us that if the line drop is to be the same in both lines so that $P_{45} = P_{190}$, the diameter of the low-pressure line must be 1.27 times that of the high-pressure line. The steam temperatures are 384 deg., respectively, and if we assume an outside temperature of, say, 80 deg. we shall have approximately—

$$\frac{\text{heat loss at 45 lb.}}{\text{heat loss at 190 lb.}} = 1.26 \times \frac{293 - 80}{384 - 80} = 0.89$$

Hence if the lines were designed for equal total line drop, the low-pressure line, under ordinary outside conditions, would lose something like 10 per cent. less heat than the high-pressure line.

But suppose that we let the drop be 10 times as great in the high- as in the low-pressure line, so that $P_{190} = 10P_{45}$. Then Equation [7] gives us $D_{45}/D_{190} = 2.02$, and in this case for 80 deg. outside temperature we have approximately—

$$\frac{\text{heat loss at 45 lb.}}{\text{heat loss at 190 lb.}} = 2.02 \frac{293 - 80}{384 - 80} = 1.41$$

so that the heat loss would be considerably less for the high-pressure line. The figures are, of course, only roughly approximate, but they suffice to show the advantage of using high-pressure transmission with a small pipe and large line drop, altogether aside from questions of the capital cost of the line.

Although we have no precise data which would enable us to estimate the probable change in the combined furnace and boiler efficiency caused by changing from low to high pressure, it would seem, in view of the foregoing reasoning, that unless the transmission line is very short, a properly designed high-pressure plant may be made decidedly more economical in operation than a low-pressure one for the same heat supply to the vulcanizer.

Babbitt as Material for Light and Heavy Bearings

Minimum Wear on Shaft Due to Composition of the Metal—Wearing Qualities of Good Babbitt—Oil Grooves Easily Cut—Various Grades for Different Uses—Method of Handling

By W. S. STANDIFORD

BABBITT as a material for light and heavy machine bearings does not seem to be used to the extent that it deserves; which is due, no doubt, to a lack of information as to its merits as a bearing metal and also to a prejudice against its use on various machines caused by ignorance in handling, as workmen can make the most expensive and high-grade babbitt appear worthless, in regard to the length of time a bearing lined with it will last and the trouble such a metal will make during the operation of machinery causes many factory owners to keep it out of their machine bearings.

Babbitt and brass are mostly used all over the civilized world as a bearing metal on various classes of machinery; both giving good results if they are of fine quality and well made, also suited to the weight of moving parts and plentifully supplied with grease or oil, care being taken not to let such bearings run dry. Brass is an excellent metal for journals and it gives fine results when constantly looked after. In these days of efficiency methods and rapidity of operations, the human element cannot entirely be ignored, and sooner or later, a factory's oiler will neglect to supply a brass bearing with oil when it needs it the most, a cut shaft and bearing resulting in a loss of time and money until the machine can be started again. The oiler in these cases mostly putting the blame upon dust working into a bearing and clogging it up, etc.; when in reality it was his own fault.

Brass and Babbitt

Brass has serious disadvantages when contrasted with babbitt ones which are as follows: owing to its composition, it is a metal that heats up rapidly if for any cause the flow of lubricant becomes irregular or intermittent; heating makes the brass expand rapidly, this in turn causes both shaft and bearing to be pressed together too tightly, the lubricating oil getting rubbed off their surfaces, a "frozen" bearing as it is technically termed, resulting. On the other hand, due to babbitt metal having altogether different characteristics from brass, it will stand more abuse (not that it is advisable to ill treat any machinery), and will run longer before a bearing cuts and seizes a shaft as compared to brass. Babbitt proves to be a very suitable composition for machinery bearings; its advantages in this respect are so great where smooth running machines are desired with the least wear on shafts, that this material gives the utmost satisfaction in factories when it is rightly looked after.

The fine wearing quality of babbitt is due to the fact that it has a more dense grain and also a greasier nature than brass. This gives to it great anti-frictional qualities, thus such a metal will run very much cooler under equal conditions than brass or any other metal. As babbitt can be melted in an iron ladle over any fire, great rapidity in replacing worn bearings in machinery breakdowns is a most desirable feature and also a money saver. In addition, oil grooves can be easily and quickly cut, or if preferred, cast ready made by the millwrights or machinists repair forces using asbestos cord. Uniform bearings are easily obtained in casting such bearings when care is observed in doing the work. Babbitt also has another valuable money-saving feature conferred by its low melting temperature, that allows the use of a portable forge for melting purposes, thus enabling all work to be done on the spot near the engines or other machines. This saves time by eliminating walking of the workers to and fro from the job, to the lowest possible extent.

This metal deadens noise, and last but not least, is cheaper than brass. There are a variety of different grades of babbitt on the market adapted to various machine requirements, such as high pressure and fast speed journals, medium pressure and medium speed and also low pressure and fast speed metals generally contain more tin and antimony with a small amount of copper; while the low pressure and medium speed metals usually have smaller quantities of tin and antimony and a large amount of lead. Tin, antimony and copper confer hardness to babbitts; so it will readily be seen that those who prefer to make their own formula for use in various classes of machinery bearings, can easily regulate its hardness to suit all requirements. There are many varieties of babbitts on the market so that any manufacturer who desires to purchase his own instead of having it mixed at his plant by the repair forces will have no difficulty in selecting a grade suitable for various machines; of course, taking into account the work they have to do as the conditions of working differ in various factories.

Most Suitable Grade

The methods of handling by workmen also have a great influence on the length of time bearings will last. None but high grade men should be employed to re-babbitt bearings. Personally, the writer thinks that, except for a few special cases, two kinds, one a lead-base alloy and the other a tin-base one are sufficient for the average class of machine journals, rolls being included in this list. But each metal ought to be of the highest possible grade that can be made. Rarely are bearings made entirely out of solid babbitt, except some very small ones including those made on die-casting machines, these latter are cast complete with oil grooves, etc. They need only to be turned and faced off before using. In general use, is used only as a lining in bearing shells of cast iron, malleable iron, brass and bronze.

Steel castings were found out by experience to be unsuitable for this purpose on account of warping tendencies when the casting strains are removed by machining. Cast iron shells on account of their cheapness and great strength, are most commonly used for stationary machines, also some malleable ones for the same purposes. The latter class gives fine results in machines which are subjected to heavy vibrations. The railroads generally make use of bronze shells so as to insure the completion of their runs and keep their time schedules as accurately as possible. Bronze or brass shells with a babbitt lining are also made use of extensively in the automobile trade. From the foregoing facts it will readily be seen the esteem in which this metal is held as a bearing material in different lines of manufacture. Owing to varying sets of working conditions encountered in shops and mills, it is necessary to use babbitts of such a composition as will prove suitable in order to have all machinery operate with the least amount of trouble.

Long Wearing Composition

Thus bearings carrying a heavy weight and rotating at high speed, need a metal whose ingredients are varied and also mixed in such proportions so as to obtain the best results. The formula given below is one that has been found out by long experience to give good satisfaction in journals supporting a weight of 2,000 lbs. and moving at a rate of 185 revs. per minute; it being one that enables machinery to continue in action for long periods of time assuming that lubrication is attended to regularly before bearings need replacing.

Formula For a Long Wearing Journal Babbitt

1,400 lbs. lead.
232 lbs. antimony.
165 lbs. alloy. (Tin and antimony mixture.)
5 lbs. bismuth.

In making up this mixture, there is needed a cast iron pot and also some ladles of various sizes; the latter should be of the self-skimming type having a

welded bridge across their spouts so as to prevent dirt and dross from getting poured in with the babbitt. This iron bridge also prevents splashing and enables a good sized stream to be poured. A supply of mandrels, clamps, etc., will also be required by machinist's or millwright's repair forces. In making up the formula listed, experience shows that it is best to melt the tin and antimony alloy and bismuth in a crucible separately from the other ingredients; this is necessary because of the fact that it takes a greater degree of heat to melt them, than lead, as it is a matter of great importance in melting babbitt, (whether it is purchased ready for use or made on the premises) to avoid burning as the latter produces heavy shrinkage in all lining shells, besides reducing its antifrictional qualities.

Mixing the Metal

Such a mixture is also rendered dirty and softer in texture, causing all burnt bearings to wear out rapidly during the operation of machinery equipped with this metal. It is better to melt the lead components in an iron pot until it becomes fluid and then add the well-stirred antimony and bismuth mixture stirring frequently; after which, allow the alloy to remain upon the fire for awhile longer so as to make sure every ingredient is thoroughly melted and mixed. This ensures even wearing journals, the amount of time depending upon the bulk of metal melted. Powdered charcoal or else sawdust should be kept on its surface to prevent oxidation and a formation of dross by the action of the air.

(To be continued.)

ORIGIN OF BALATA

The origin of balata gum, which forms the base of balata belting, dates back about 400 years. It was originally used by the Incas Indians to make crude suits of bull-hide armour, which they had to wear in order to protect themselves against the fatal effect of poisoned-tipped arrows. These suits of armour were composed of two plies of bull-hide, which were welded together with balata gum which they procured from the Bocla tree. These suits of armour were found by the Spaniards at the time of their conquest of that country and were subsequently transferred to European museums as historical relics. The balata gum used in the making of these suits of armour still retains its full strength unimpaired. The same result is obtained by using the Lanco impregnation process in the manufacture of balata belting.

EFFECTIVE BELT SPEED

Practice is still rather uncertain about the ratio of horsepower and belt width, despite the many views—or, perhaps, in consequence of the many views—expressed by investigators. Wider belts for heavier loads sums up the apparent requirement. Speed investigations recently were expressed in the formula that belt speed is almost exactly in proportion to the width of the belt. In relation to high speeds the effect of centrifugal action must be considered, and the conclusion is expressed that nothing is gained by operating a belt in excess of 4,000 ft. per minute. It may be seen from the particulars given, that horse-power increases directly as to speed up to 4,000 ft. per minute, and that at 5,000 ft. per minute the effective tension or pull is reduced about 10 per cent. The preference should be for a maximum of 4,000 ft. To secure transmission at a higher speed it becomes necessary to increase the tension of the belt to a point beyond economical operation.

The centre lip should be at about 45 deg. to the cutting lips of the drill. The drill is in best condition when the chip comes out in a close coil.

Taking Moisture From Compressed Air

MOISTURE is mixed with air in the form of transparent and invisible vapor, until a humidity of 100 per cent., or the point of saturation, or the dew point, is reached and this dew point is always reached in compression and transmission of air at ordinary working pressures, say six atmospheres or 75 lb. gauge. Immediately when this point is passed, the excess moisture condenses into actual water but is still mixed with air. The saturation point of air constantly varies, and is determined by its pressure and temperature, especially the latter and, at a fixed temperature, any given volume of air is saturated when it contains a certain quantity of water vapor. Now, if the absolute pressure of a certain quantity of air is, say doubled, by which the volume is reduced ½, the moisture carrying capacity is reduced the same proportion so that if the humidity of free air is 50 per cent., this humidity becomes 100 per cent. when air is compressed to two atmospheres (15 lbs. gauge) and if compressed to six atmospheres (75 lbs. gauge) the humidity becomes 300 per cent., and 200 per cent., of the air will refuse to carry water as vapor if the temperature remains constant.

As air is compressed its temperature rises rapidly and with each rise of about twenty degrees its capacity for carrying moisture is doubled. Starting with free air at sixty deg.; as it is compressed to 75 lbs. gauge, its temperature at delivery no matter how perfectly the compressor cylinder may be water jacketed, will be about 300 deg., so that in consequence of this change of temperature, the capacity of the air for moisture will have been doubled so many times that when it leaves the cylinder the real humidity will be quite low although it still carries all the moisture with which it started.

When the air is lowered in pressure, as is the case when being used for operating pneumatic tools, air rammers, or any other use where the kinetic energy is converted into work, this excess moisture will show up in the form of water and the water content will be very noticeable where the air is delivered into much lower temperature than that at the compressor. If however this compressed air is pre-cooled to a temperature not in excess of that of the point of delivery or usage, the moisture will be precipitated at the point of pre-cooling and a separator placed between the pre-cooler and point of delivery will eliminate the moisture and deliver dry air, provided the moisture removed does not in any way come in contact with the air passing through the separator.

In many cases there is sufficient cooling surface in the pipe line, which is exposed to atmospheric temperature, that it is not necessary to install after-cooler; however the following tables will enable you to determine whether or not there is sufficient cooling surface in the pipe line or if after-cooler is required the approximate size can be figured from the table showing required cooling surface for free air delivered. The following table shows the length of pipe containing one square foot of cooling surface:—

Size,	External Surface,	Internal Surface
¾ in	3.637	4.635
1 in.	2.904	3.645
1¼ in.	2.301	2.768
1½ in.	2.01	2.371
2 in.	1.608	1.848
2½ in.	1.328	1.547
3 in.	1.091	1.245
3½ in.	.955	1.077
4 in.	.849	.949
4½ in.	.764	.848
5 in.	.687	.757
6 in.	.577	.63
7 in.	501	.544
8 in.	.443	478
9 in.	.397	.427
10 in.	.355	.382

* As suggested by the United Machine and Mfg. Co.

HIGH OR LOW PRESSURE FOR STEAM HEATER

(Continued from page 21)

The information requested may be summarized as follows:

a The use of a reducing valve in a steam-heating line does not, in itself, have any effect on the economy of the heating.

b If a steam motor is substituted for the reducing valve, the heating value of its exhaust is decreased by the amount of heat turned into work by the motor.

c Line drop is merely distributed throttling and has no direct effect on the final heating value of the steam.

d By generating at high pressure and transmitting through a small line, with large line drop, the heat loss from the line may be made much smaller than when the pressure is low throughout the system.

European Central Power Stations

By C. W. E. CLARKE,
Power Engineer Dwight P. Robinson & Co.

ONE NOT acquainted with the conditions surrounding the electric light and power industry in England and on the Continent is apt to meet with a succession of surprises because of the lack of similarity in methods and also because central station development in those countries is at a decidedly earlier stage than ours. Greater London, for example, instead of having a few large central stations is supplied with light and power from more than forty separate plants. The majority of these, moreover, are not along the Thames, as one might except, but are located in various parts of the city and are operated by means of cooling towers. The main reason for this peculiarity is not hard to find when one remembers that Greater London is composed of many boroughs or districts, each of which, in general, has its own light and power supply.

London Stations

The largest plant in the London district and one of the largest in England is the Lots Road Station of the London Electric Railway Company, with a total capacity of 83,000 kw., consisting of six 8,000 kw. machines, one 15,000 kw. and one 20,000 kw., the latter two just recently installed. All turbines are of the Parsons type with generators made by the Metropolitan Vickers or old British Westinghouse Company. This station was originally built by Chapman, an American engineer connected with Yerks at the time the so-called "Tuppenny Tube" was constructed in London.

Two other stations in Greater London are the Poplar Station and the Grove Road Station. The former is a small municipal plant supplying the Borough of Poplar and is of no particular interest other than that it has one of the earlier installations of air pre-heaters which is still giving a good account of itself. The Grove Road Station of the Central Electric Supply Company is a privately owned enterprise. This station operates on cooling towers and originally contained reciprocating engine units which have since been changed for turbine units. At present the plant contains one 10,000 kw. and two 6,000 kw. units and a 15,000 kw. machine is now being installed—all of the B. T. H. type. This plant is a very creditable piece of reconstruction work on old property and is interesting also because of its peculiar load condition, the summer load being about half the winter load, which —by the operating of all cooling towers in summer—enables the plant to maintain approximately the same vacuum throughout the year.

Other British Stations

On my visit to The Rugby Works of the British Thomas Houston Company, I had the privilege of inspecting their latest construction on units of from 5,000 kw. to 15,000 kw.

Another plant, of interest because of its underfeed chain-grate stoker installation, is the Wolverhampton Corporation Electric Supply plant at Wolverhampton. Chain-grate stokers in England are usually either the so-called Underfeed or the Babcock & Wilcox type. The Underfeed design for forced-draft stokers is somewhat different from the usual type of chain-grate with which we are familiar, inasmuch as it has its own fans mounted on the stoker frame with fans and grate operated by one motor. This makes a very attractive and self-contained unit. The Wolverhampton plant has a capacity of 23,000 kw., consisting of two 1,000, one 2,000, one 4,000 and three 5,000 kw. turbo-generator units.

Several plants of The Birmingham Corporation Electric Supply Company were inspected. The Summer Lane plant, the largest, is an old plant with a capacity of 34,000 kw., consisting of two 5,000 kw. turbine sets, twelve 1,500 kw. engine-driven sets and six 1,000 kw. low-pressure turbines. The company is completing a new plant called "Nechells" which is to have an ultimate capacity of 105,000 kw., the first installation consisting of two 15,000 kw. units. The plant is to be operated on cooling towers. The steam pressure will be 325 pounds with superheat at 272° F. The boilers are of the Babcock and Wilcox type and, in accordance with the usual practice abroad, are fitted with economizers. Draft is produced by the so-called Prat system, an induced draft system operating by discharging a fairly high-pressure blast of air through ejector nozzles in the centre of the stack, thereby creating the required draft for combustion. The stacks which flare from the bottom are rather grotesque in appearance. It is interesting to note that this plant is also equipped with so-called "iron-clad" switch gear. Buses and all connections to switches are run in steel, box-shaped conduits which are filled with insulating material after the buses are installed. It is expected that the "Nechells" plant will be in operation this Fall.

At Manchester there is the Stewart Street Station of the Manchester Electric Supply Corporation, a plant of 92,500 kw. capacity consisting of one 4,000 kw. engine-driven unit and one 7,500 kw., one 5,000 kw., three 6,000 kw., one 15,000 kw., one 18,000 kw. and one 25,000 kw. turbo-generator sets. The Manchester Company is also building a new station at Barton designed to contain at present three 25,000 kw. turbo-generator units. At the time of my visit, the steel work was completed and the building was about ready for the installation of equipment. The Barton station should prove to be an interesting development since it is one of the newer designs and contains, among other up-to-date features, a very complete heat reclamation system. They expect to have this plant in operation the latter part of the year but, judging from the condition of the work, I am inclined to think it may be some time later before they go into actual operation.

I had the pleasure of going through the works of the Metropolitan Vickers Company, a large turbine manufacturing concern at Birmingham, and in my opinion the products of this company, especially the turbo-generator units, are the finest in Europe. In fact, I question if they are not better in some features of design and construction than the turbines we are using in this country. They are building machines regularly of from 15,000 kw. to 25,000 kw., the popular size apparently being the 15,000 kw. machines. The character of the work and the general design are excellent. One novel feature is the provision for steam extraction for feed-water heating by installing the heater as an integral part of the turbine base. This method has a great many advantages and I would expect to see machines along these lines built in this country before very long.

The Dalmarnock Station at Glasgow is a relatively new development with an ultimate capacity of 200,000 kw. The present plant operates under 275 pounds steam pressure and 300° F. superheat. In my opinion this is the best plant I saw in England. It is operated under commercial load at a heat consumption of between 18,500 and 19,000 B.t.u. per kw.-hr. with coal containing about 12,000 B.t.u., a very good record especially when it is considered that the yearly load factor is less than 30%.

The Clydes Mill Station of the Clyde Valley Electric Power Company, near Glasgow, was visited. This has two 5,000 and two 15,000 kw. turbo-generator units. The main features of interest about this plant were the two large units which were built by the Metropolitan Vickers Company.

European Stations

In France I visited four stations, all in the environs of Paris. The Saint Denis, Saint Ouens and Issy les Moulx Stations of the Compagnie Parisienne Distribution d'Electricité and the Gennevilliers Station of the Union d'Electricité. The main interest in the first three stations lies in the use of the Belleville type boiler, a rather remarkable piece of equipment and so unlike a boiler as we know it as to cause remark from Americans. The tubes are

threaded into the tube header and further held in place by lock nuts.

The most interesting station in Paris is the new Gennevilliers Station, designed to contain ultimately 200,000 kw.; three 40,000 kw. units are now being installed and the two remaining units are on order. This station is more American than any on the Continent and shows the ear-marks of the designer's visit to this country about three years ago. Unless trouble is encountered with the condensing equipment, which looks rather small, I expect this station to prove to be one of the best in England or on the Continent. It is especially noteworthy because of the large size of the units and the air pre-heaters with which the boiler plant is equipped. This is the largest installation ever attempted along these lines and the result should prove interesting. The boiler plant is arranged with three parallel lines of boilers, two rows of Babcock & Wilcox with chain grates and one line of large Stirlings, double-fired by Riley stokers. The Babcock & Wilcox boilers are set rather low, but the Stirling units have very fine combustion space provided for them. This plant was starting to operate at the time of my visit and should soon be in service.

In general both in England and on the Continent the usual practices of construction and design differ materially. In central station work especially one sees the mark of the manufacturer rather than of the engineer, the latter apparently accepting without very much question the opinion of the manufacturer as to how apparatus should be installed and utilized. This is particularly apparent in the setting of boilers, which both in England and France are still set very low with small combustion spaces. It is not uncommon to see a 1,500 h.p. boiler set with the front header 8 feet or 9 feet from the floor, whereas today 15 feet to 20 feet would be considered good American practice. The almost universal use of economizers is another noticeable point of departure from our practice, for their installation is apparently in no way controlled by load conditions, cost of fuel, etc. The use of air heaters is becoming more general, although I saw no good representative installations of heaters in operation. Several are under construction, however, and by this time the installation at Gennevilliers is very likely in operation.

The European method of rating boilers is another point of departure from our custom, inasmuch as they base ratings on evaporative capacity, a logical method except where a boiler is designed for a certain number of square feet of heating surface. In this case, due to variant ideas of builders as to what constitutes good practice in terms of evaporation (in pounds of water) per square foot of heating surface, the relative evaporation rates might be radically different.

Some of the structural steel designs used abroad are worthy of comment. Apparently there is a very general tendency to use heavy rolled shapes in designing columns and beams, while from our point of view the use of plates and angles would be better practice. For example, I-beams with channels riveted on both flanges are used for columns, and I-beams with single or double cover plates are used in place of girders. In the construction of large steel skeleton buildings the sides are covered for the full height with temporary scaffolding. Apparently the present-day hanging scaffoldings widely employed in this country are not used. However, in considering all these matters it is necessary to realize that the builders in England are in the hands of what is called the Board of Trade, a rather arbitrary governmental organization which sometimes does not permit the use of methods or devices which we consider good practice on the ground that they are dangerous operations. This very likely has some bearing on what, off-hand, we would consider un-economical design.—The News.

POWER EXPOSITION AND THE ENGINEER

The National Exposition of Power and Mechanical Engineering which is to open at the Grand Central Palace on Thursday, December 7, for a week, except for the intervening Sunday, will clearly demonstrate to the general public that the engineer is a tremendous force in civilization today.

We are living in an age made possible by the utilization of inventions and researches, but of the millions of people in the world only a few hundred thousand have any definite conception of the multitude of great ideas that have been put to work for the benefit of humanity.

Thousands of individual engineers are daily challenged by the problems involved in the provision of materials for our buildings of steel, cement and glass which are lighted by electricity, served by mechanical elevators and heated and ventilated by the power and heat from natural sources, but in distinction to the doctor and lawyer these individual engineers do not see their clients. The beneficiaries of their services may be on the other side of the globe.

To show the general public how much it needs the engineer is a very important purpose of this Exposition. But, further, engineers themselves, to be successful must specialize and few can keep in touch with the great strides that are being made in other fields of engineering than those with which they have immediate contact.

The great diversity of exhibits insures the particular appeal that this Exposition will have to all engineers as it will permit them to learn quickly and thoroughly of the progress in the arts and sciences of mechanical engineering. All industries using heat or power in any form will be interested in the displays of steam turbines, steam engines, steam boilers, feedwater heaters, superheaters, economizers, metering devices, stokers, coal handling apparatus, valves and pipe fittings, and the thousand and one important details that enter into what is known as a power house. Each of the exhibitors is planning to emphasize in an instructive way the features of his product which denote progress. In this way not only will the men who understand and use these devices be benefited, but the general technical man and the public will have a greater understanding of the intricate problems involved in the production and use of power plant apparatus. The scope of the Exposition includes mechanical machinery and machine tools such as are included in any completely appointed machine shop and is such that benefit will accrue, not only to the engineers of the great cement, ceramic, metallurgical and power generating industries whose fuel and power problems are severe, but also to the industrial manufacturer whose power costs are a relatively small part of the total cost of manufacturing his product.

The attendance of mechanical engineers and those specializing in refrigeration is assured by the scheduling of the Exposition at the close of the meetings of The American Society of Mechanical Engineers and the American Society of Refrigerating Engineers. The opportunities for professional fellowship which these meetings offer will be extended through the week of the Power Exposition. The American Society of Mechanical Engineers will have a headquarters booth at the Grand Central Palace at which all of the members will be made welcome and services extended. Members of both of these societies will be admitted to this Exposition by display of their badges or on presentation of their membership cards.

FLASH POINT OF OILS

Inasmuch as it is impossible to state from purely scientific determinations the probable hazards of any particular petroleum or petroluem product, the industry has for a long time determined the flash point as an indication of the temperature of danger, states the Bureau of Mines in Serial 2,400, "Fire and explosion hazards of petroleums and petroleum products." The flash point of an oil may be stated as the lowest temperature at which it gives off vapors in sufficient quantity to form a flammable mixture with air. The higher the temperature at which flash occurs, the less is the hazard of an oil from fires or explosions. Information regarding the determination of flash points is given in Serial 2,400, which may be obtained by addressing the Bureau of Mines, Washington, D. C.

A plant for manufacture of asbestos products, the first of its kind in Canada, is being erected at Asbestos, Que., to cost $100,000. At present the raw material is shipped out of the country and imported as a finished product.

Practical Help of Technical Paper

THERE ARE many men who are inclined to deny that a technical paper is of real help to them in the practical problems of everyday life. We venture to say that if this is the case, it is more the fault of the man himself than of the technical paper. Cases are continually coming to our notice of advantage being taken of some particular article by a reader who reads with intent to profit. Only the other day we met a man who frankly admitted that after reading a recent article on the handling of fires to prevent clinkering, he had reduced his labor by a considerable amount, and incidentally saved his employer considerable fuel. Perhaps a number of other men who read that same article read it with their minds already made up that they knew more about it than the author.

Probably one of the hardest things in the world is to convince a man who has been doing a job a certain way for a considerable length of time, and getting away with it, that he is not using the best, or even the right way. The old school fireman is one of the greatest examples of this kind of settled conviction. The writer has had experience with a considerable number of firemen who were excellent men under certain conditions, but who could not be persuaded to alter their methods when those conditions changed. Invariably when it would be pointed out to them that their methods, while good in some places, were the wrong ones for the job of the moment, they would take the attitude that they had been successfully firing for ten, fifteen or twenty years, and knew all there was to know about it.

We take an example of the above kind, knowing it is an extreme one, but perhaps useful for that reason. If a man approaches an article in a technical paper with the idea that there is nothing he can learn, he will not learn. If he only reads one article, on a subject which he is interested in, but reads it thoroughly, and remembers or takes notes of it, he will get benefit from it. On the other hand if he skips lightly through the magazine, glancing at the illustrations and the head lines, he will retain about as much of its contents as he does of the daily paper.

The man that reads a technical paper and reads it thoroughly is put in contact with a means of gathering information that he could not get in any other manner. The technical paper has an outlook which embraces the whole world, and developments in engineering which would never be noticed by the daily press, are received and published by the technical papers. On the other hand, developments in fake engineering which are usually played up large in the daily press, are only noticed by the technical press for the purpose of exposing their false claims. Information found in a technical paper is always substantially correct, and if it should slip, there are enough keen critics to quickly point out the error.

To the man who is following his vocation in the smaller places, where he may but seldom have the opportunity of coming into contact with men in the same line as himself, the technical paper provides a real link between himself and the rest of the world. He can be kept just as much in touch with events as the chief engineer of the largest plant in the largest city in the world. If the paper did nothing more than remind him every two weeks or month as the case may be, that there are other plants and other places in the world, it would be worth spending the nominal amount involved.

Boiler Inspection Laws

FROM TIME to time some correspondent raises the question of the boiler inspection laws of the Province of Ontario, as is the case with L. J. E. in last issue, and "Inspector" who replies to him in this. The question of what are and what are not adequate laws, is one that cannot be disposed of by only looking at it from one angle. From the engineer's point of view, the more stringent the laws are the better he should be pleased, because after all, boiler inspection is a safeguard of the lives of engineers as well as of the property he has charge of. On the other hand boiler inspection laws enforced without a good measure of common sense, may be entirely right as far as safeguarding life and property are concerned, but may very seriously interfere with the legitimate carrying on of industry. There is no doubt an unfortunate division of authority as far as the Government is concerned in the method of boiler inspection, and due to it there may no doubt be cases where boilers escape inspection altogether. The matter of who is a fit and proper person to make a boiler inspection has been touched upon in these columns before, and we say again, that the fact of a man holding an engineer's certificate is not sufficient qualification to make him a competent person to inspect a boiler. A man who is undertaking the serious responsibility of deciding whether or not a boiler is fit for service or not should be a specialist in boiler knowledge, as well as an engineer. We say as well as an engineer, because a boiler inspector should be primarily an engineer, with knowledge of operating conditions, to give him the necessary experience to fit his special knowledge to everyday problems. In the case of the insurance companies, every inspector's report is carefully scrutinized by one or more men who have specialized for many years in this business, and who are familiar as a rule with the history and construction of the boiler in question, the conditions under which it has operated, and the historical record of similar boilers under similar conditions for many years past. In the light of this experience a defect or condition which might be dismissed by the ordinary man as of little moment, may appear much more serious to the chief engineer or his staff in the office.

It would manifestly be impossible to pass a law that would satisfy everybody concerned, for no law has ever done that. The best that can be done is for the operating engineers, the manufacturers, insurance companies and Government departments to meet from time to time and frame such regulations as will ensure the greatest degree of safety with the minimum of inconvenience to all concerned.

The Operators' Point of View

24 Hour Daily Consumption of Fuel Based on Calorific Value of Coal And Boiler Load as Determined by Actual Evaporation. Boiler Efficiency 70%.

PRACTICAL EFFICIENCY CHART

By Thomas Parkes

Master Mechanic Crabtree Mills

The following chart, made up from actual observations, may prove of use to readers of Power House. The chart shows in the first column the calorific value of the coal per pound in b.t.u., the second column being the pounds coal per boiler horse power per hour, while the succeeding columns show the consumption at different horse powers, with a boiler efficiency of 70 per cent. These figures, as before mentioned, have been tabulated from actual evaporation tests.

ONTARIO BOILER INSPECTION LAWS

Editor, Power House:

In the last issue of Power House, (October 20, 1922) there was a letter criticizing our Boiler Inspection Laws. No doubt every law on our statute books could be criticized; however, the fact remains that nearly all our laws are far in advance of the requirements of our present industrial requirements. From time to time the various laws and regulations are amended to meet the advances made in the arts and industries. The Ontario Boiler Inspection laws and regulations, have been no exception to this rule. The fact is that the Boiler Inspection department, as such, is of comparatively recent creation, and while it has been administered very efficiently under Mr. Medcalf, yet there is nothing in the records of Ontario Boiler Explosions to warrant any radical change at this time. The mill owners and factory managers are apparently satisfied with the present arrangements. The Boiler Insurance Companies employ competent boiler inspectors who look after the safety of nearly all the high pressure boilers, and surely the large amount of risk carried as boiler insurance is sufficient guarantee to provide for public safety.

Next to the mill owner or manufacturer in point of interest comes the stationary engineer who has to look after the boilers. Few of them, if any, have indicated any dissatisfaction with the present Boiler Inspection Laws. Further in view of the fact that we have had comparatively less boiler explosions than any other province, I submit that it is the surest evidence that we have not only the best Boiler Inspection Laws in the country, and perhaps in the world, but our laws are enforced more consistently than elsewhere. While "any person obtaining permission in writing from the Deputy Minister of Labor, or any licensed engineer may inspect a boiler" under the Factory Act, yet it has been wisely provided in the Revised Statutes R. S. O., 1920, c. 229, pt. 1, paragraph 57, section 5 (a and b) that such "person obtaining permission in writing" shall give evidence that they have had the training and experience to give their judgment, further they must be reliable and of good character. It seems to me quite proper that the design, construction and installation of boilers should be under the Department

of Public Works, while the operation of same should remain with the Factory Department. Further, viewing the matter from the economic side, one can readily understand that to provide sufficient inspectors under either the Factory or Works Department to meet the needs or the requirements of the manufacturers for frequent and urgent inspections (usually on a Sunday) would mean a burdensome expense because of the incidental traveling expenses, fees, etc. Experience has shown that such traveling inspectors would be employed only 10 per cent of their time on actual inspection and 90 per cent. in traveling and waiting; whereas the licensed engineer is always available and is paid only for actual time while making the inspection. Needless to say this extra or occasional fee is now appreciated by the engineer.

"Inspector."

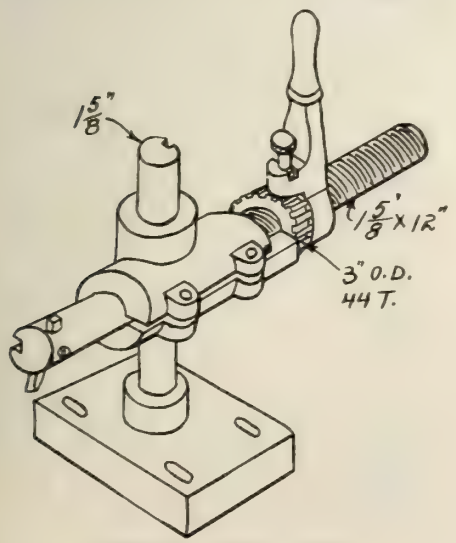
COMMUTATOR TURNING DEVICE

By D. A. Hampson

There were quite a number of direct current dynamos and motors in our vicinity and it fell to our lot to true up the commutators when in bad shape. Besides the larger ones, there were even more of 1 h.p. to 5 h.p. size but these latter were dismounted and the armatures removed for putting in the lathe. It is of those that were more advantageously trued up right in position that we will here consider.

We had an 18-in. planer that wasn't used much and we frequently took the cross rail off, trucked it to a plant, and turned the commutator at night or on a Sunday, using the cross feed for turning, the vertical feed for positioning the tool, and blocking the entire rail up to bring the tool on a center line. These jobs came so numerous and the time spent changing the planer being a dead loss (for the customer) that we made up the portable device shown by the drawing.

This has a flat cast iron base which is attached to some part of the dynamo pedestal, either by tap bolts or through bolts and a clamp. Where we could not conveniently do this, we got permission to put in two or four holes to fit our slots. The upright post shown permits a wide range of adjustment in that direction for the saddle which is bored a close fit and supplied with key and set screw.



Commutator turning device.

At right angles to the vertical post, is the tool shaft and bored hole to fit. For this, the casting is split and binder screws put in, making it possible to snub up as tight as the tool shaft can be fed. The far end of the shaft is cut with a 12 thread screw long enough to permit a movement of 9 inches. A steel nut is made a close running fit on this thread and has ratchet teeth cut on its periphery, to be engaged by the pawl set in the cast iron handle whose hub also rides on the threaded shaft.

An extension of the saddle casting is bored so the steel nut may be dropped in the recess and one half of it is cut away as shown. This provides the stationary member from which the feed movement is obtained. The tool shaft is splined full length. The cutting tool is held by a set screw at the near end. This device is easily portable, can be set up in less time than a machine tool slide, and its use does not tie up a machine. In the six years of its use, it has paid for itself many times over.

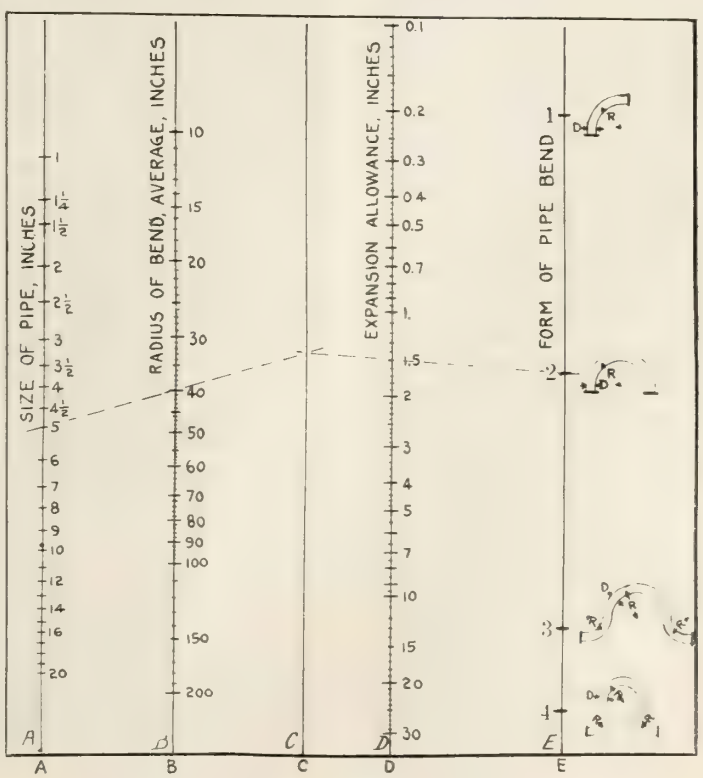
A USEFUL PIPE BENDING CHART

By W. F. Schaphorst

Here is a chart that will be found valuable and convenient for determining the average radius of bend that should be given to common forms of pipe bends, numbers 1, 2, 3, and 4, as shown at the right, column E. Or, knowing the radius of bend, the size of pipe, and the form of bend, column D gives the expansion allowance of that bend.

For example a five inch pipe was made to a radius of 40 in., the bend being a common U-bend as shown by No. 2 in column E. What expansion may be allowed? The dotted line drawn across this chart shows how it is used. Run a straight line through the 5 column A and the 40 column B and locate the intersection with column C. Then from that point of intersection run over to the mark in column E opposite the figure 2 and the intersection through column D gives the answer as 15 inches expansion allowance.

Similarly if the expansion allowance, the form of bend, and the size of pipe are known, the average radius to which the bend should be made may be determined in the same way. In other words knowing any three of the four factors given in columns A, B, D, and E the fourth or unknown factor is easily determined by following the method as explained above. This chart is based upon the following much used and well-known rules: For bend No. 1—Square the average radius of bend in inches and multiply by 0.0026 and then divide by the outside diameter of the pipe in inches. Bend No. 2.—Same as No. 1 but use 0.0052 instead of 0.0026. Bend No. 3—Same as No. 1 but use 0.0104. Bend No. 4.—Same as No. 1 but use 0.013. In the chart all of these operations are already performed—the radii are squared, exact outside pipe diameters are employed, and the proper factors are used.



Pipe bending chart.

FEED WATER AND BOILER CORROSION

Despite the continued advances in internal combustion engines, steam plant continues to keep up with the times, it is noteworthy also that boiler plant which did not, up to a few years ago, keep pace

engine and turbine design is now showing marked signs of improvement, water tube boilers in conjunction with superheaters now being the order of the day in all but some special cases where the Lancashire type still holds its own. There is a tendency to still higher pressures while American engineers are constructing very large boilers, mainly of the vertical tube type. These conditions together with the very high evaporation rates now common render corrosion a very important matter, demanding its prevention at all costs in modern boiler installations.

Naturally the prevention of most corrosion troubles lies in obtaining a suitable feed supply, not always an easy matter.

Suspended impurities can be removed by filtration, mechanical filters are ideal for this purpose, being self contained, simple and effective.

Chemical compounds are far more troublesome while air and oil often present greater difficulties still. The latter of course comes from the condensate, the former would be present in the water to start with.

The chemical compounds such as the sulphates and carbonates of lime and magnesia will form scale if allowed to enter the boiler which in turn will cause overheating of plates and tubes. Periodic scaling is the obvious remedy if they are allowed into the boiler, such methods are of course cure rather than the better method of prevention. These carbonates and sulphates are soluble in hot water hence their deposition in the boiler; in cold water they must be artificially deposited, which is, in fact, exactly what feed water purifiers seek to effect.

In the first place however the water must be analysed, upon the result thereof depends the method of treatment, in general this takes the form of introducing lime to deal with carbonates and soda to deal with the sulphates, a combined process being applied when an excess of carbonic acid is present, this being a very injurious element. There are several well known forms of apparatus on the market for dealing with these impurities, which work on the precipitation principle by different methods, heat being applied in some cases.

The main point about them is that they add or should add the reagents necessary in due proportion to the quantity of water passing for treatment, while some are continuous and others intermittent in action.

They are generally effective and reliable, simplicity being an essential to success. For small plants not warranting their expense the injection of carbonate of soda into the feed is a simple and effective method of preventing incrustation while the several patent compounds have their respective merits.

In marine boilers magnesium chloride is another element that is apt to give trouble. Its action is severe on the heating surfaces, it will especially attack tubes at points where they are comparatively dry, these points being spots where steam bubbles are mainly generated, this condition of steam generation being an established fact, that is to say, steam is not generated evenly over the whole heating surface of any boiler. The resulting deposit of magnesium chloride will produce hydrochloric acid which will bite and even eat through the metal.

For this reason it is most important that dry pipes be fitted in boilers for carrying away the steam, especially when superheaters are used, otherwise magnesium chloride will be carried away with wet steam only to dry on the superheater tubes or projected on to the steam surfaces above water level, with the effect mentioned.

Air in feed water is perhaps the most difficult element to deal with.

It takes a considerable time to boil air out of water, soft deposits can of course be removed by periodic blowing out but air requires degassing methods to entirely eliminate it. A system of continuous blowing down is now practiced by some engineers. It has the advantage of permitting the contents of the boiler to be renewed pretty frequently without a shut down, eliminating mud before it has time to accumulate and allowing the use of carbonate of soda to reduce the bicarbonate of lime. The latter is then decomposed into carbonate which is in turn disassociated.

The water containing caustic soda and carbonate of soda can then be used to purify the make up feed with continuous blowing down methods. One apparatus which works on this principle consists of a steam separator, a reservoir for receiving the blow down liquor and a chamber into which the purified blow down water is drawn off the steam passing into a feed water re-heater, soda being added in the proper proportions through a water meter.

For removing air from water one of the best known methods is that of spraying the feed water into the steam space, means being provided to prevent its getting into the steam pipes, while another is to feed at the usual level exernally and to carry the feed pipe internally and to carry the feed pipe in in a jet which sprays against a hood. Both methods do effectively remove air from the water but unfortunately it is liable to be carried into the superheater and even turbine and engine cylinders where it may do damage, while in the superheater extensive and rapid corrosion of tubes may be set up by the air eating away the natural protective coating of magnetic iron oxide which forms therein.

In order to eliminate oxygen, and air dissolved in water may contain as much as 33 per cent. of oxygen, degassing is necessary. This may be done by agitation and subjecting the water to a vacuum as in the Weir and other systems or by chemical methods. In the latter case highly oxidisable iron is used to absorb the oxygen; the system is employed in Germany and elsewhere but is still in its infancy.

Rusted iron is used. The French system now being developed in England is in the form of iron vessels through which the water either flows alternatively or has its direction periodically reversed. The last named method is somewhat ingenious utilising as it does the iron reaction to cause it to work on the regenerative principle. It is essential in any method of degassing to prevent the water from coming into contact with air after it, while it is advisable to heat it to the highest temperature before feeding.

Oil in water is a trouble that concerns principally boilers supplying reciprocating engines, it being practically non-existent with turbines. It is almost impossible to keep the feed free from it. But with very oily engines it can to a certain extent be eliminated by co-agulating it by means of alumina-ferric, subsequently neutralising the acid and filtering. The main trouble caused by oil is its tendency to spread over the surface of the plates and tubes and so prevent the direct contact of the water with them thereby setting up overheating.

Mechanical oil separators are of course a good deal used. They depend mostly on a sudden change of direction of the exhaust steam, baffles, etc., it being essential in high vacuum condensing plants to keep the baffle plates moist.

The oil can be drained off by some form of automatic trap.

In small steam plants more or less elaborate methods of treating feed water may not be feasible, but in view of the high duty demanded by modern boilers of even moderate size it is most essential that the feed water should be carefully attended to otherwise disaster may occur and as it usually does so when least expected these precautions are not only warranted but positively imperative.

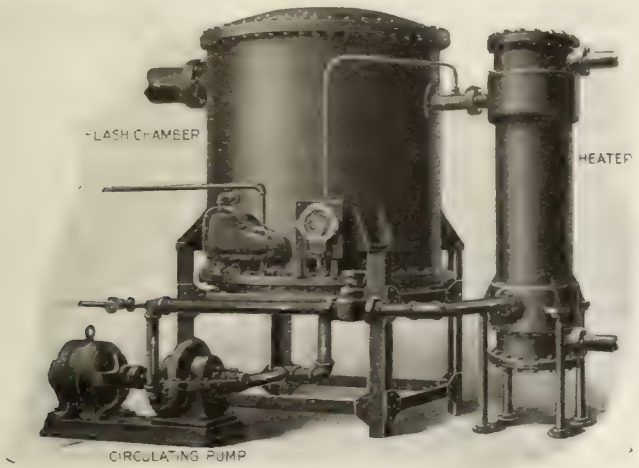
LEAKAGE OF NATURAL GAS FROM PIPES

R. A. Cattell, natural gas engineer of the Bureau of Mines, who is making a special study of transmission losses of natural gas, plans to conduct a series of tests on sections of pipe to determine the relation of leakage to pressure. Although practically all the gas companies have been interested in the subject of transmission losses, comparatively little work has been done to determine certain fundamental facts, such as the effect of pressure on line losses.

SENSITIVENESS OF GASOLINE VAPORS TO IGNITION

Further tests have been conducted at Pittsburgh, Pa., by the United States Bureau of Mines to obtain data as to the comparative sensitiveness of gasoline vapors and methane with respect to their ignition from electric flashes. This work has a bearing on the degree of protection that will be necessary for electric motors used in and around buildings where gasoline vapor may be present.

Progress in New Equipment



THE FLASH Evaporator shown in the accompanying illustration is a new departure in the production of pure boiler feed water.

It consists essentially of a tubular heater, an evaporator proper or flash chamber maintained under vacuum, and a circulating pump. A distilling condenser is also used if the vapor does not pass directly from the flash chamber to the main condenser—otherwise no distiller is required.

The raw water is heated in the tubular heater to a temperature that is both below the boiling point at atmospheric pressure and also below the temperature at which the impurities in the water are deposited as scale. This temperature, to which the water is heated, is, however, higher than the temperature corresponding to the vacuum maintained in the evaporator. The circulating pump maintains the water in the heater under pressure, and as this heated water enters the evaporator, it flashes into vapor due to the vacuum existing therein.

The flash evaporator is well adapted for small, as well as large installations. The distillate produced is practically pure water—when salt water is used as evaporator feed the salt content of the distillate is less than 6 parts of salt in 100,000 parts of water.

Distilled water is cheaply obtained because exhaust steam instead of live steam is used in preheating. In plants where there is not sufficient exhaust steam for operating the system, the additional steam required can be taken from the low pressure receiver of the reciprocating engine or from one of the lower stages of the turbine.

The formation of scale in the heater and the precipitation and accumulation of other solid impurities are eliminated; such scale-forming impurities and other salts remain in solution during the entire evaporation process, because of the low temperature at which evaporation takes place, and because no evaporation can occur on the heating surface of the water heater. The system can be operated continuously.

This non-scaling evaporator not only provides the necessary pure make-up water, but it also supplies this water free from dissolved and entrained oxygen, and hence corrosion of boiler tubes, piping, economizer tubes, etc., is eliminated.

An automatic feed control valve maintains the water in the flash chamber always at the same level.

The internal structure of the flash chamber is so arranged as to divide the incoming water into a multitude of thin films. This splitting of the water into slices or films is one of the outstanding characteristics of the flash evaporator, and is one of the features wherein the flash evaporator differs from apparatus in which the raw water is ordinarily boiled in a large mass just like a large body of water in a tank.

The flash evaporator described is manufactured and distributed by the Schutte & Koerting Company of Philadelphia.

STEAM JET ASH REMOVAL COSTS

The problem of ash handling from the boiler room has been considered a routine drudgery of the worst kind—dirty and dusty, hot and unattractive, haphazard and costly.

With the introduction of the steam jet ash conveyor the operator was relieved of the dirty and disagreeable features but the steam consumption was a variable quantity. Even with the newest equipment steam consumption would exceed expectations.

According to the Green Engineering Company, East Chicago, Indiana, manufacturers of the Green Steam Jet Ash Conveyor, this condition of uncertainty of steam consumption has been met by their REMOTE CONTROL feature which measures the steam and controls the human element in operating the steam jet system.

Briefly this REMOTE CONTROL consists of an electrically operated steam valve; a steam operated water valve and an air flow meter with a clock and chart.

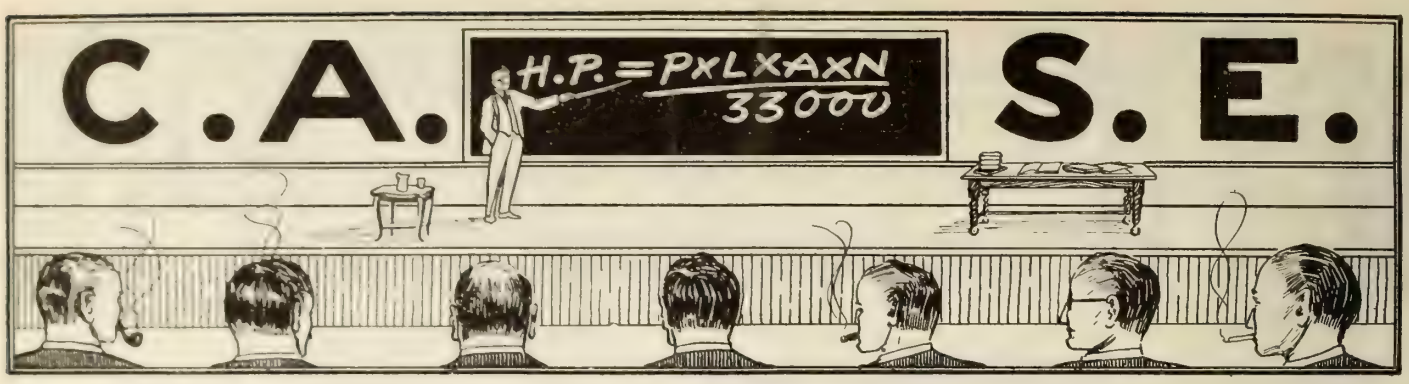
Its operation is as simple as the ordinary steam jet system with the added insurance of control of steam flow and a record of how the ash removal has been accomplished.

When ready to hoe ashes into the intake the operator puts his foot on a button or board and closes an electric switch with his foot. The closing of this switch operates a solenoid in the steam valve leading to the steam jet nozzle. The solenoid opens the steam valve. Located between the steam valve and the steam jet nozzle is a steam line which connects the main steam line to a water spray nozzle. Pressure of steam in this steam line opens the water valve and the water spray functions.

As soon as the operator lifts his foot the switch opens automatically; steam pressure closes the electric valve; and the water valve closes because of lack of steam pressure.

The air flow meter gives a permanent record of the minute by minute suction maintained on the system. It tells the story if the operator lays a brick or stone on the switch and permits the steam to flow while he is not hoeing ashes into the system. This is shown by the nature of the line drawn on the chart. While the system is in proper operation the pen will record jagged lines. When no ashes are being removed the line will be straight along the curvature of the chart.

The Green Engineering Company claim that from a study of actual operating conditions in numerous plants it has been shown that a saving of half the present steam consumption is possible due to the control of the human element in operation.



C. A. S. E. AND EDUCATION

Editor, Power House:

Dear Sir: Your editorial re R. A. S. E. and the C. A. S. E. having similar problems is well taken.

The membership of the C. A. S. E. is composed of all types of engineers, from directors and teachers in various technical schools, mechanical, combustion, electrical, refrigerating, steam and operating engineers, and so on down the line, to the third and fourth class certificate holders.

The educational meeting opens by answering any questions that may be in the Question Box, then proceeds on to the regular educational program. By this it can be seen that any problems that a member needs answering immediately, is soon solved, from such a varied membership.

The present educational program is a splendid one as can be seen by any reader looking up the program in the Power House, August 20th issue.

If there are any drawbacks to it the following examples show the causes: A member is interested in combustion, he turns up to the meeting and the theme is refrigeration for that evening. Another member is interested in dynamos and motors and he decides he will attend a meeting, only to find that there is a demonstration on valve setting of various types of engines and pumps. On another night the theme is, we will say, to be on heat losses and how to prevent them; the member who should attend this discussion goes to a card party or to the theatre or again it may be that he goes to a lodge meeting. Then he wonders how he missed that particular discussion. All these men were at fault in not keeping themselves posted to the educational program, but the last man brings up another problem, that is, which is the best night to hold these meetings.

C. A. S. E., Toronto No. 1, is about to solve the last problem, as membership is increasing so rapidly that in the near future, meetings will be held every night, and there will be classes each night for the different grade certificate holders. By this any member can choose his own night and all may learn from A to Z, engineering in all its phases and from all angles.

I must admit that the educational programs have in the past been of a hit and miss character to the individual member, but one must agree with me that, no one course of papers or list of questions on the various engineering subjects could be drawn up to equally suit all requirements of such members.

I think that now your editorial has brought the subject up it would make a good discussion among engineers to the advantage of all concerned as to "what line of education should be pursued to meet the requirements of such a diversified body of men."

Yours truly,
Geo. A. Brown,
Secretary.

QUESTIONS ON EDUCATIONAL COMPETITION

Subject.—Boilers, Furnaces, Supports And Settings

(1). What are the principal requirements to be taken into consideration when designing a boiler or before putting it into service?

(2). What type or types of boilers have the highest circulation; and is there any objection to a very high circulation?

(3). Assuming the design to be perfect what conditions might obtain either internally or externally to interfere with the circulation?

(4) What relation has the heating surface of a boiler (in different types) to the normal rated-capacity; and what is the limit if any of pounds evaporated per sq. ft. of heating surface per hour?

(5). How should boilers be supported; and what are the regulations for the different types and sizes?

(6). How high above the grate-bars should different types and sizes of boilers be set; and does it make any difference whether it is long or short flame coal which is to be used?

(7). Is there any advantage of using hollow instead of solid furnace walls; and what are the objections to hollow walls rather than extra cost?

(8). How can radiation losses be reduced other than by dead-air space; and would the saving be warranted by the expenditure? Prove it in the case of two boilers 66 in. x 16 ft. 6 in. using 950 tons of bituminous coal (12,500 B. T. U.) at $8.00 per ton.

(9). If one B. H. P. rating is the equivalent of 30 lbs. water evaporated from 100° F. into steam at 70 lbs. pressure, what is the total number of B. T. U.'s required to evaporate same; also the equivalent number of lbs. coal (13,000 B. T. U.) assuming an overall efficiency of 70 per cent.?

(10). If you were called upon to make an inspection under the factory act, what would you look for; and how high would you carry the hydrostatic test?

(11). Why is the girth seam of a H. T. boiler or steam drum stronger than the longitudinal seam? Why is the stress in the girth seam only one half of that in the longitudinal seam?

THIRD SERIES OF QUESTIONS

(1) Give a list of combustibles, with their relative heating value in B. T. U.

(2). What part of the air enters into combination with combustibles?

(3). What are usual products of combustion in the case of (a) coal; (b) oil; (c) wood?

(4). What is the average amount of air required to burn a pound of (a) coal (b) oil; (c) wood; and have perfect combustion result in each case?

(5). What means is there of knowing when you have attained perfect combustion?

(6) What effect does excess air have on the furnace temperature and on the temperature of the exit gases?

(7). What is meant by draft and what is the cause of Natural Draft?

(8) What means is there for measuring or indicating draft?

(9) What is the difference between Induced and Forced Draft?

(10) What effect have air leaks in boiler setting and on the draft; and how would you locate and determine the extent of them?

Geo. J. Soucy,
Chairman.

NEW BRANCH FORMED

On Thursday, Oct. 6th, acting upon an invitation from Mr. James Nichol of Thorold, Past Grand President A. W. Sweet, and Grand Secretary L. J. Ellis, visited the engineers of that district for the purpose of giving them some information as to the aims and objects of the C. A. S. E.

After short addresses by Messrs. Sweet and Ellis, the latter gave an illustrated lecture on A. C. motors and alternators, which was enjoyed by all present, and it was decided to form a lodge of the C. A. S. E. in their town. This was duly carried out, and Messrs.

(Continued on page 33)

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

OIL IN CONDENSATE

Question:—We are using the condensate from a surface condenser for make-up in a cooling pond, and have been experiencing some trouble on account of oil in the water, which becomes deposited on the condenser tubes. We use the condensate as make-up for the circulating water in order to save scale deposits on the tubes, but if we have oil it is just as bad. What would you advise to get rid of the oil?

Answer:—We should think that the most satisfactory method of getting rid of this trouble would be by installing a pressure filter between the condenser and the cooling pond. If there are periods of shut down at week ends or nights one filter would be enough, but if the plant is running continuously then the filter should be installed in duplicate. A settling tank of ample size might be sufficient to allow the oil to separate from the water, and float to the top. The overflow to the cooling pond could be situated about half way up the height of the settling tank, so that any solid matter in suspension could settle at the bottom, while the oil and grease would float to the top. A filter could be constructed from a square or round tank, containing perforated screens covered with cheese cloth or Turkish toweling. There are many good pressure filters on the market and this would be the most satisfactory way out of the difficulty.

CLICK IN FLYWHEEL

Question:—I am operating a Wheelock engine, and there is a loud click in the flywheel every time it makes a revolution, with occasional exceptions. I have tried the nuts on rim and hub, and also the key, and they all seem to be quite tight. Could you suggest the cause and possible remedy for this condition?

Answer:—It is very difficult on a case of this sort without being on the spot, but would say that you should first of all make absolutely sure that there is no side slack in the key, and that the bolts are quite tight. You can test the tightness of the key by the use of feelers and by observation. The key might be quite tight top and bottom, and sound solid to a hammer, and yet allow a slight play on the sides. If you get a man to stand by the valve gear, and move the crank to and fro from each side of the centre, bringing it to a stop each time, and at the same time stand at the fly wheel and watch carefully each time the crank is moved you may be able to detect by oil squeezing out or actually by a slight movement of the shaft before the wheel moves, that there is a side slack on the key.

If you are quite satisfied that there is nothing slack on the flywheel, then the noise is probably coming from some other portion of the crank shaft, and sounds as though it were in the flywheel. If your crank shaft is a very small amount out of line, it will cause a side slip on the crank pin which could easily be mistaken for a noise in the flywheel.

You do not say whether there is a belt driven from the flywheel. If there is, perhaps the belt may be causing the noise, as the splice passes over the wheel. About the only thing to do is to go over every part that might be making the sound, and by a gradual process of elimination to reach the actual cause. How about the wedges in the main bearing nearest the wheel? Is there any slack on the forward or back quarters of the bearing that would allow a movement in the shaft at the dead centres? The wedges themselves can cause a click such as you mention, and that would sound as though it was in the flywheel.

FUSIBILITY OF COAL ASH

Data regarding the softening temperatures of coal ash from several hundred coals from the different fields of the country are contained in Bulletin 209, "Fusibility of ash from coals of the United States." by W. A. Selvig, assistant analytical chemist, and A. C. Fieldner, supervising chemist, just issued by the Bureau of Mines.

Information concerning the fusibility of coal ash has become of considerable value to the consumer of coal, mainly in connection with the troublesome formation of clinker resulting from the melting of the ash constituents of the burning coal. The growing interest in such data has led the Bureau of Mines to make a general survey of the "fusing" or "softening" temperatures of the ash from coals of the United States. It is hoped that this information, when used together with the large number of coal analyses published by the bureau, will assist the consumer of coal in comparing different coals, and in selecting the coal best adapted for his purpose.

Coal ash is the incombustible residue remaining after the complete combustion of coal; it is derived from the inorganic mineral constituents of the coal. The ash-forming constituents are (1) inherent or intrinsic impurities that are present in an intimate mixture with the coal substance, and are derived either from the original material or from external sources such as sedimentation and precipitation while the coal-forming plant remains accumulated; (2) impurities, formed either during the laying down of the coal bed or subsequently, that occur in the form of partings, veins, and nodules of clay, shale, slate, pyrite, and calcite; and (3) impurities that become intimately mixed with the coal in the process of mining, such as fragments of roof and floor.

Coal ash is composed largely of compounds of silica, alumina, lime, and iron, with smaller quantities of magnesia, titanium, and alkali compounds.

Bulletin 209 may be obtained by addressing the Bureau of Mines, Washington, D. C.

NEW BRANCH FORMED

(Continued from page 32)

Sweet and Ellis initiated and installed the officers for the coming term.

Thorold No. 39 started off under a combination of the so-called fatal 13. There were 13 members to start, the number of the branch was 3 times 13 or 13 times 3, and the date was the 26th, another multiple of 13.

The officers and members of the newly formed lodge are all enthusiastic engineers and are going to make their lodge one of the most progressive in the C. A. S. E.

The following are the officers for the present year:

President, J. Leitch; vice-pres., Jos. Conway; sec., C. Davis; treasurer, Jas. Mcgarry; conductor, C. Hudson; door keeper, A. Watson; P. pres., John Nichol.

The thanks of the Grand Lodge are tendered to Bros. Conway and Jas. Nicol for the interest they have taken in organizing the lodge.

Practical Electricity for the Power Plant Engineer

By G. R. ARCHDEACON, A.M.I.E.E.

ONCE upon a time (not so very long ago) the most complicated piece of electrical machinery to be found in the average power house, was the simple electric bell, and as a result the average mechanical engineer was not impressed by things electrical.

To-day things are different, the rapid progress in the design and construction of electrical machinery has been simply phenomenal, and has rendered it imperative that the operative engineer should make himself profoundly familiar with electrical engineering as well as mechanical engineering.

The brief survey given to this subject of the rapid increase in electrical development in the last issue of "Power House" is indicative of the importance to which all things electrical have now to be considered.

To become a "good" electrical engineer, it is first necessary that one should be a "good" mechanical engineer, as the very foundations of the application of electricity are mechanical considerations, such as strength of materials, theory of structures, stresses and strains, mechanical drawing, foundry work, machine tool operation, laws of friction and lubrication, etc.

As the power house engineer is frequently called upon to advise concerning the adaptability of some form of electrical machinery for a particular service in his plant, it is desirable that some little time should be devoted to the study of the special characteristics of the various forms of electrical machinery with which he is likely to come into contact.

In approaching this subject it is necessary that we return to the subject of magnetism, and again briefly review its peculiar relationship to all forms of electrical machinery.

If we pass a few turns of wire round a piece of soft iron, and then connect the end of the wire to a source of d. c. current, the iron will instantly become a magnet.

One end of this magnet will be a south pole, whilst the opposite end will be a north pole.

From each end of this magnet vast numbers of magnetic lines of force will be radiating.

These magnetic lines of force are known as the magnetic field.

Within certain limits, the greater the number of turns of wire which are wound round the piece of iron, or the stronger the amount of current sent round the wire, the greater will be the number of magnetic lines of force radiating from the poles of the magnet.

In other words if we wish to increase the magnetic field, it is only necessary to increase the number of ampere-turns round the piece of soft iron, such as the pole pieces of a dynamo.

It will therefore be readily understood that there is always a magnetic field about a wire through which a current of electricity is passing. This can readily be proved by experimenting with a compass and a length of wire connected to a source of d. c. current.

As the north and south poles of a magnet depend upon which way the current is flowing, it is frequently necessary to be able to quickly determine one from the other.

(a) Grasp the wire by the right hand with the thumb pointing in the direction the current is flowing, the fingers will show the direction of the magnetic field.

(b) Grasp the coil in the right hand, so that the fingers point in the direction in which the current flows, the thumb extended will point to the north pole.

It will be readily realised that there will be certain grades of metals that will be more easily acted upon by these magnetic lines of force, than others. In other words certain metals will have a greater magnetic resistance, whilst others possess a greater "magnetic conductivity."

We must therefore get a thorough grasp of these factors.

Permeability

Is the ratio between the number of lines of force per unit area passing through a megnetisable substance, and the magetising force which produces them.

In other words it is the ease with which magnetism passes through any substance.

Magnetic Flux

The total number of lines of force in the circuit.

Magnetomotive Force

Is the force similar to electro-motive force, in other words, magnetic pressure.

Reluctance

Magnetic resistance, being the resistance offered to the magnetic flux by the substance magnetised, and is the ratio of the magnetomotive force to the magnetic flux.

Magnetic Saturation

Is the point where a large increase in the magnetising force does not produce an apparent increase in the magnetisation. The state of a magnet which has reached the highest degree of magnetisation.

Possibly by considering the analogy which exists between magnetic circuits and electric circuits, the above conditions may become more clearly understood.

(a) Electric circuits, according to Ohm's law.

$$\text{Electric current} = \frac{\text{electromotive force}}{\text{resistance}}$$

$$\text{or Amps} = \frac{\text{volts}}{\text{ohms}}$$

(b) Magnetic circuits.

$$\text{Magnetic flux} = \frac{\text{magnetomotive force}}{\text{reluctance}}$$

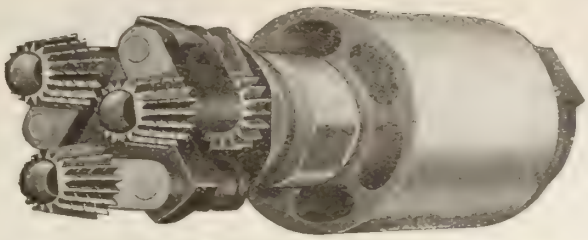
Reduced to practical units this would be

$$\text{Maxwells} = \frac{\text{gilberts}}{\text{oersteads}}$$

Reluctance is directly proportional to the length of the circuit, and inversely proportional to its cross sectional area.

This is calculated as follows:—

$$\text{Reluctance} = \frac{\text{length in centimetres}}{\text{permeability x cross section in sq. cent.}}$$

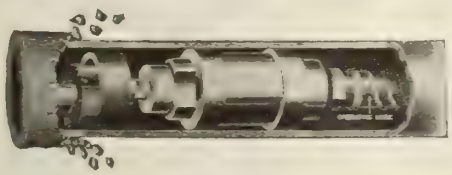


Standard Water Driven Tube Cleaner

KEEP YOUR BOILERS CLEAN

Lagonda Water Driven Cleaner for Curved Tubes

Lagonda Air Driven Cleaner for Straight Water Tubes



Cleaner Removing Scale from Outside of Fire Tube

All natural waters contain some impurities which, when introduced into a boiler, may appear as solids deposited on the heating surface. No matter what the substance consists of, it must be removed at frequent intervals or it will decrease the capacity and efficiency of the boiler and may cause it to be badly damaged by over-heating.

Some waters, notably well waters, deposit such quantities of scale that they should be purified before going into the boiler, thereby preventing an accumulation of incrustation and consequent damage to boiler parts, and at the same time effecting a large saving in fuel by keeping all parts of the heating surface in a clean and efficient condition. If you have bad feed water it is a case for the chemist, for the scale is probably composed of several substances which must be known before the exact treatments necessary to get rid of them can be determined upon. The use of treatment without technical advice is poor policy.

Stony and vegetable matter in suspension can be removed by FILTERS, which we supply in various sizes and designs to suit all requirements. In most Canadian plants, lake or river water is used for feed, and these waters seldom carry large quantities of scale-forming materials in solution. Scale can be allowed to form in boiler for a considerable period. Experience in each individual plant determines the limit at which tube difficulties will begin or a perceptible falling off in efficiency will take place. With such a limit of scale formation fixed, and the danger of allowing it to be exceeded, well understood, probably the most economical and efficient method of keeping the heating surfaces clean is by use of the LAGONDA TUBE CLEANERS.

The cleaners are designed and so constructed as to thoroughly remove all the scale, in the shortest possible time, at the lowest cost of operation, and they require a minimum amount of repairs, reducing both the waste boiler time and labor cost of cleaning.

They are made to operate by either water, air or steam. In every case a swing head is furnished so designed that three sets of cutters are thrown out by centrifugal force against the scale in such a manner that they make straight line contact with the tube and they do the work without damage to it.

You can be supplied with LAGONDA tools for cleaning Economizers, Condensers, Evaporators and other tubular plant.

WE SHALL BE VERY GLAD TO FURNISH FULL PARTICULARS

BABCOCK & WILCOX, LIMITED

HEAD OFFICE FOR CANADA - COLLEGE ST. (ST. HENRY), MONTREAL

TORONTO OFFICE, BANK OF HAMILTON BUILDING

Hans Christian Oerstead, a Danish scientist, discovered in 1820 that a magnetic field surrounded a wire through which current was flowing from a voltaic battery, yet it remained for our famous Englishman, Michael Faraday, on October 1st, 1831, to cause a current of electricity to become induced into wire from a magnet.

On this date Faraday wound on a wooden block an insulated copper wire 203 ft. long, and over it another insulated wire of equal length. One circuit was then connected to a galvanometer and the other to a battery of 100 cells. Faraday then noticed that at the instant the current began to flow in the wire connected to the battery, a brief current in the opposite direction traversed the other wire in the galvanometer circuit.

Working upon this discovery as a basis for further experiments he succeeded on Oct. 17th in realising his dream, by obtaining a current of electricity from a permanent magnet.

From this date the world can be said to have possessed an electro dynamo, and all electric dynamos, motors, alternators, transformers, etc., in existence to-day may be truly said to owe their origin to this most remarkable Englishman.

Faraday's Law

When a conducting circuit is moved in a magnetic field so as to alter the number of lines of force passing through it, a current is induced therein, in a direction at right angles to the direction of motion, and at right angles also to the direction of the lines of force, as viewed from the point from which the motion originated.

To prove this great theory, it is only necessary to take an ordinary horseshoe permanent magnet and a length of copper wire. Connect the ends of the wire to a galvanometer, make a loop of the wire and pass this loop quickly up and down between the poles of the magnet. The needle of the galvanometer will be seen to oscillate, thus proving that a current of electricity has become induced into the coil of wire.

The modern dynamo and alternator are not made up with permanent magnets such as Faraday used, electro-magnets being used instead.

This is because of the ease with which we increase the magnetic flux, by increasing the power of the magnets; this being accomplished by increasing the ampere-turns round the electric-magnets.

Remember that to cause a current to flow, or become induced into a loop of wire, it is imperative that we cause "a change in the number of lines of force passing through the loop of wire."

The greater the number of lines of force changed in passing through the loop the greater will be the voltage induced in the said loop.

Let us therefore now consider the practical application of these laws to the practical dynamo or alternator.

It is usual to keep these two terms separate, using dynamo to distinguish a d. c. generator, from alternator the a. c. generator.

The word generator is not quite the correct term to apply to either of these machines, as neither of them actually "generates electricity." As the word is popularly employed we may continue to use it in a somewhat restricted sense.

A dynamo and alternator may therefore be considered as machines for changing the number of lines of force passing through the loop of wire. thereby resulting in an electromotive force being developed in the loop of wire by inductance.

In the case of the dynamo there are three principal parts:—Field magnet, armature, commutator.

Field Magnets

These are to provide a magnetic field, and are so constructed that the intensity of this field may be increased or decreased as required.

The magnetic lines of force emanating from the "pole pieces" of these field magnets pass through the loop of wire on the armature.

The Armature

The armature is a "form" upon which the loop of wire is wound. As the armature is rotated between the pole pieces, the number of lines of force being "cut" by the loop of wire varies according to the relative position of the loop with regards to the lines of force.

The Commutator

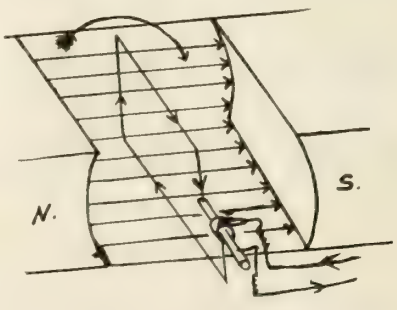
The commutator is a device for changing the alternating currents which are generated in the armature, into direct current.

When the armature is rotated between the pole pieces a current is induced in the loops of wire on the armature. The quicker the armature is turned, the higher will be the voltage induced therein.

The magnitude of the electromotive force induced in the loop depends upon the rate at which the number of lines of force are changed in the loop, therefore the quicker the loop is turned, the higher will be rate of change.

The direction of the current induced in the loop will depend upon the direction of the lines of force, and the direction of the loop.

It is important that we should be able to readily ascertain the direction of the



induced current, as this knowledge decides for us the positive and negative poles of the external circuit.

There are several rules laid down for our guidance in the matter, amongst which the best known are as follows:

Fleming's Rule

If the forefinger of the right hand be pointed in the direction of the magnetic lines, and the thumb (at right angles to the forefinger) be turned in the direction of the motion of the conductor, then will the middle finger (bent at right angles to both thumb and forefinger) show the direction of the induced current.

Ampere's Rule

If a man could swim in a conductor with the induced current, then the north seeking ( ) pole of a magnetic needle placed directly ahead of him will be deflected to the left, while the south seeking pole ( ) will be urged to the right.

The Palm Rule

If the palm of the right hand be held facing or against the lines of force, and the thumb in the direction of the motion, then will the fingers point in the direction of the induced current.

In taking as an example an elementary idea of a dynamo, we assume it to consist of only a single loop of wire on the armature. It will be obvious that the number of lines of force passing through this loop will vary according to the position of the loop. When this loop is vertical to the lines of force, the maximum number of lines will pass through it, but when it is horizontal, or laying parallel to the lines of force, no lines will be passing through the loop, therefore whilst in this position no current will be induced in the loop.

It will therefore be apparent that the voltage will be continually rising and falling according to how near or far away the loop is from the position in which it is cutting the maximum number of lines of force.

Therefore twice in each revolution the value of the voltage will go from maximum to minimum.

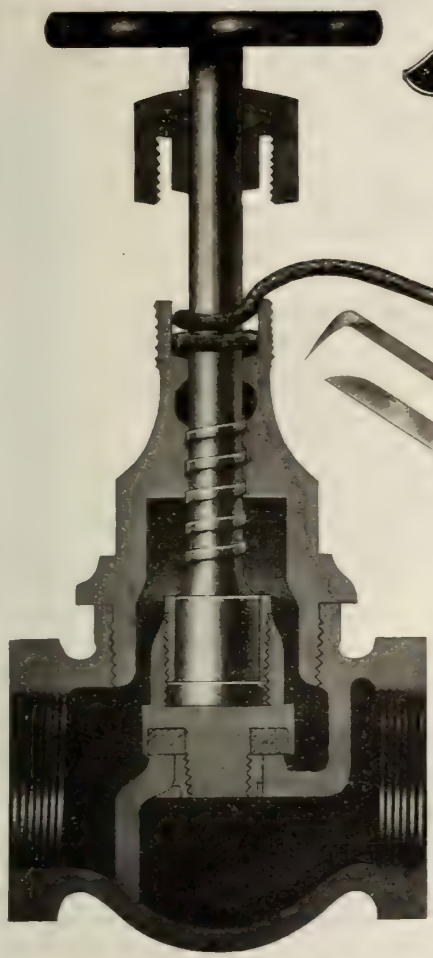
If the armature be rotated slowly these changes will be most apparent, and as the speed of rotation is increased the variation will become less and less obvious to the naked eye.

As there is a limit to the speed we may attain, there still remains another way in which to overcome this difficulty, and that is by arranging another loop on the armature. If this is spaced half way between the original loop we will reduce the voltage variation by one half with a result of apparently giving a steadier voltage. Therefore by continuing to increase the number of loops round the armature we finally arrive at the stage when these fluctuations are of such a short duration that they cannot be detected by the naked eye when the current goes off on its journey to illuminate the electric lamp.

For the generation of one volt it is necessary that the loop of wire (or inductor or conductor, as we shall henceforth term it) should cut one hundred million lines of force per second.

Raybestos PACKINGS

"They Wear Longest"



Reduce Your PACKING Investment

IT MATTERS not whether it be a valve plunger, cylinder head, piston rod or any other operation—you will secure the utmost in service and reduce your packing cost by consistently using **Raybestos.**

Raybestos Packing is Heat-Proof and Acid-Resisting — and it will not harden. It reduces costs.

Raybestos is made from Asbestos secured from Canadian Thetford Mines -— its quality is assured.

There is a Raybestos Packing to meet every requirement of your plant. Specify Raybestos Packings. "They Wear Longest."

The Canadian Raybestos Co., Limited

Peterborough, Ontario

RING PACKING
Style 325

SPIRAL PACKING
Style 425

The equation for finding the voltage of any dynamo is as follows:

Let n = number of conductors in series.
n = number of revolutions per second of the armature.
p = number of magnetic poles.
Φ = magnetic flux per pole.

Then the flux cut per second by any conductor is $n \times p \times \Phi$ lines.

Dividing by 10^8 gives the average volts.

If there are n conductors in series the total e. m. f. is:

$$\frac{n \times p \times n \times \Phi}{10^8}$$

From an inspection of this formula it will be seen that the voltage of the generator can be changed by changing either the speed n or the flux, or the number of poles, p, or number of conductors n.

The last two of course are fixed when the machine is built; the first two can readily be changed by the operator, and afford a practical means of controlling the voltage.

The practical way to control the voltage is by having an adjustable resistance called a field rheostat inserted in the field circuit. By this means the number of ampere-turns round the pole pieces can be varied.

The turns round the poles are of course a fixed quantity, but by means of the field rheostat the amps flowing through the turns is varied, and as ampere-turns is the ratio of amperes × turns a change of either quantities effects the equation.

A rise or fall in speed always has a great effect on the voltage, and it is for such a reason that all engines for driving dynamos must have very delicate governors, and be well balanced, otherwise the speed fluctuation of the engine becomes apparent in the varying voltage of the dynamo, which results in more rapid depreciation of the electric bulbs, and renders the electric light unsuitable for illumination.

NEW BOOKS ON MECHANICAL STOKERS

One of the most interesting publications of the year in the mechanical stoking field is the new bulletin, "Cutting the Cost of Producing Steam," just published by the Detroit Stoker Company, of Detroit, Michigan.

The bulletin starts with the promise that "One of the conditions necessary to the efficient combustion of coal is the uniform liberation of the volatile gases. This is a condition which practically never can be obtained in the hand-fired furnace. Inasmuch as the hand-fired furnace also represents definite limitations in the way of utilizing the cheapest grades of fuel, engineers are today finding that the way to improve boiler room operating conditions is to install mechanical stokers."

From this point the bulletin takes up the dollars and cents value of mechanical stokers, dealing with each of the savings effected, in detail. It next deals with the application of advanced engineering principles and modern stoker design, and then concludes with a section on the service of the mechanical stoker, unique in its treatment.

The bulletin is a beautiful example of the printer's and engraver's art, as well as being one of the most readable and interesting pieces of literature put out in the power equipment field. Complimentary copies will be forwarded to interested engineers and executives upon request.

BULLETINS

The Combustion Engineering Co. have issued a very interesting little booklet on the subject of service, under the appropriate title of "Service Bulletin." This booklet has been published to show exactly the kind of service that stoker manufacturers give to their clients and prospective clients, and also shows that this service has to be covered in the selling price of the apparatus. This results in some clients having to pay a certain proportion of the service charges, when they do not require such service. They are helping out the other customer who does require considerable service, but only pays for a portion of it. The suggestion is made that service should be a definite separate charge, paid for according to the exact amount of service given.

The Young Pump Co., 310 Lister Bldg., Hamilton, have issued a bulletin describing their centrifugal vacuum and boiler outfit. This self contained unit is designed for handling the returns from small heating systems, separating the air, and returning the water back to the boiler.

"Palco" is a new packing described in a folder issued by Greene Tweed & Co., makers of "Palmetto" and other brands. The new packing is adapted to hydraulic and low steam pressures. Canadian representatives are Fairbanks Morse Co.

The Quaker City Rubber Co., Philadelphia, have concluded arrangements whereby the St. Lawrence Supply Co., 167 Commissioners St., Montreal, will handle their goods in the province of Quebec.

ENGINEERS IN ANNUAL RE-UNION

At the fourth annual re-union of the Engineering Alumni Association of Toronto University, Oct. 27 and 28, engineers from all over the Dominion and the United States assembled to renew friendships and visit once more the scenes of their college days. The programme as arranged by the executive of the Alumni, was a complete one, festivities opening on Friday evening with a dinner dance. Saturday morning the year meetings were held at Varsity, all the classes from away back in the eighties down to last year, being well represented.

At the annual dinner held in Convocation Hall, Capt. C. E. MacDonald proposed the toast to the University of Toronto. In replying, Prof. A. T. DeLury of University College, made reference to the Literary and Scientific Club of olden days and said that the Alumni Association was rapidly forming closer bonds between School and the rest of the University.

In replying to the toast to the engineering profession, Dr. A. C. Humphreys, president of the Stevens Institute of Technology, Hoboken, N. J., laid stress on the point that students should be properly prepared in the essentials before commencing an engineering education. Prof. H. E. T. Haultain of S. P. S. proposed the Silent Toast, which was followed by "The School," by W. E. Douglas of the Class of '02, and replied to by Dean Mitchell of the Class of '92. General Mitchell appealed to the Alumni for scholarships saying that it was only by the individual and co-operative efforts of the Association that scholarships could be provided, and that it was in this respect that the alumni could best help the students of to-day.

REPAIRING GASOLINE TANKS

By C. Howard

Should a gasoline tank, or can which has contained gasoline, need repairs for which a soldering iron is to be used, great care is necessary in charring the container of any gasoline fumes which may be in it. If extreme care is not exercised there is a possibility of an explosion occurring. Gasoline fumes being heavier than air will remain in any container for a considerable length of time even though it has an opening to the air. There are several methods of clearing away such fumes of which turning the tank with its opening to the lowest point and leaving it so for several hours is perhaps the easiest. Another way is to subject the container to indirect heat in a similar position to that stated. It is advisable however, to keep the blow-pipe as far away as possible.

CATALOG

The Bristol Co., of Waterbury, Conn., has just issued a new and revised catalog on their varied line of pyrometers. In addition to listing the instruments the book contains a number of specimen charts taken from actual installations. There are also several pages devoted to plans illustrating the correct method of installing the recording apparatus. The application of the fire ends is clearly described and demonstrated by a number of photos and line drawings, showing their adaptation under different conditions.

Now an Entirely Underfed Side-cleaning Stoker

THE ARROWS below are the symbol of a great development in mechanical stoking. They trace the path of fuel travel of a stoker that embodies a new basic design — the "*lateral retort*" principle.

Briefly summarized the advantages of the *lateral retort* design are:

The multiple retort effect. Coal is underfed to the *lateral retorts* as well as to the main or central retort. It is not overfed from the main retort onto side grates as in other stokers employing side dump plates. Consequently, the principle has made possible for the first time; *a truly underfeed side-cleaning stoker.*

Heavy overload capacity. The *lateral retort* design provides a large reserve fuel capacity for meeting overload demands.

Low maintenance. The *lateral retort* construction also permits a simple rugged construction; only two simple steam cylinders and a few moving parts buried deep in the green coal where they cannot burn out. The simple balanced dump plates—of the type that has proved so successful in the Jones "A-C" Stoker—insure an additional saving in maintenance.

Low initial and installation cost. The extreme simplicity permits a moderate first cost, and the side dump construction does away with basement ash pits and expensive excavation. For this reason the *Lateral Retort* Stoker is adaptable to any conditions in existing plants.

The construction and advantages of this stoker are thoroughly covered by a new catalog. Ask for it.

Safety Water Columns

Reliance

Get the Most Out of Your Fuel

THE BOILER D. M. LIFE SAVER

Keeps your boiler clean and thus eliminates repair bills, besides reducing maintenance cost.

Will not injure boilers or fittings.

No acid — No chemicals — Just "D. M."

"D.M." Boiler Enamel is a Vegetable composition, absolutely harmless, and will keep your boilers clean right down to the bare metal. Prevents all scale formation, corrosion and pitting. "D. M." Boiler Enamel is used by many of the largest users of steam throughout the world, including the British Government.

Manufactured by: HOUSEMAN & THOMPSON, Ltd., Newcastle-on-Tyne, England.

Sole Distributor for Canada :

J. A. CARRUTHERS - 23 Scott Street, Toronto

LESS FUEL, MORE HEAT

Always the COLE for COAL Economy

Economy and Efficiency

are both absolutely necessary to-day with coal mounting to almost prohibitive prices.

Cole Steam Traps

will save their cost many times over in your plant in a single season, through the saving in fuel, water, oil and worry. It is indestructible. It has no wearing parts, and is visible at all times.

Let our Engineers explain them to you.

Send for a copy of "Steam Condensation," a book of vital interest to every Manufacturer.

PLASTIC FIRE BRICK

ELIMINATE LOOSE BRICK *and* FALLEN ARCHES

by using BETSON PLASTIC FIRE BRICK for repairs and for building complete, seamless, monolithic furnace linings, including front and rear arches, side walls, bridge walls and baffles.
No more fallen arches—no more in-leakage of cold air. But more power with less expense.
Shipped either mixed ready for use or dry to mix with water (the cost is the same) from warehouse stock in principal cities.
Write for valuable booklet.

THE JOHN H. McGOWAN CO.
CINCINNATI, OHIO U.S.A.

COME to the POWER SHOW

at

Grand Central Palace
New York City
Dec. 7-13, 1922

(Except Sunday)

THIS is to be the most complete exhibition of power plant equipment ever shown under one roof. A coincidence of unusual interest to POWER HOUSE readers is the fact that it will be held immediately after the annual December meeting of the American Society of Mechanical Engineers and of the American Society of Refrigerating Engineers.

Every Member of the A.S.M.E. and A.S.R.E. Should Attend

Fresh from the interesting discussions of the meetings they may go to the Grand Central Palace and inspect no less interesting exhibits of the latest developments in the power and mechanical engineering field.

The N. A. S. E. have fixed the following days for its gatherings: Friday, December 8th, New Jersey day; Saturday, December 9th, New England States and Connecticut day; Monday, December 11th, Greater New York day.

Representatives of the most progressive manufacturers of power plant appliances will be in attendance. Thousands of engineers from all parts of the country will visit the show.

Every facility for the convenience of visitors will be provided by the management, just as was done at the other expositions recently held here.

National Exposition of Power and Mechanical Engineering

Room 1102, Grand Central Palace
New York City

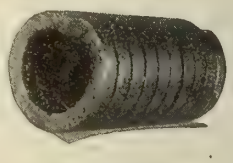
A COMPLETE SERVICE IN

"John Crane"

FLEXIBLE METALLIC PACKING

A Complete Packing Service in These Three Styles

"John Crane" 100
Babbitt foil impregnated with purest graphite and wrapped spirally. Flexible, uniform, compressible. Max. Temp. 450 F. Max Pist. Speed 400 F.P.M.



"John Crane" 300
Resilient asbestos channel with flexible metallic wearing face. Max. Steam 300 lbs.

"John Crane" 400
Resilient duck channel with flexible metallic wearing face. Max. steam 125 lbs. Max. Pist. Speed 400 F.P.M.

DE LAVAL OIL PURIFIERS

are the more economical and more efficient means of dehydrating transformer oil or purifying lubricating oil for either Diesels or turbines. Strong centrifugal force, made more effective by the De Laval system of strata distribution, effects so positive a removal of water and solid impurities that the efficiency of oil is indefinitely maintained or restored by the use of these centrifugals.

Write for Bulletin No. 105, which gives full information regarding De Laval Oil Purifiers.

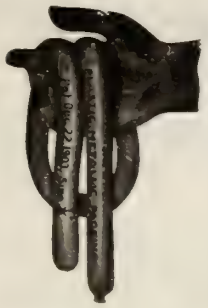
Montreal Winnipeg Edmonton Vancouver

"SAFETY" Plastic Metallic Packing



For steam, water, air, gas, etc., is practically indestructible and may be used over and over again. It is

GUARANTEED TO LAST THREE YEARS WITHOUT RENEWAL

It is made of an alloy of the finest anti-friction metals, just hard enough for long service but not hard enough to damage any rod.

The metal is combined with the best lubricating material, making it practically SELF-LUBRICATING AND FRICTIONLESS.

Send for full particulars also about our "Safety" Superheat Sheet Packing.

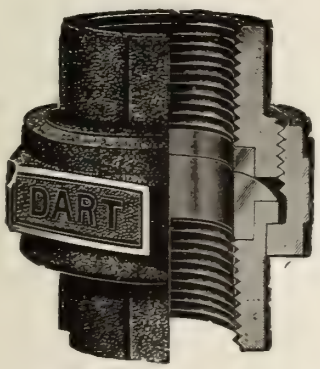
There's a Tycos or Taylor Temperature Instrument for Every Purpose

Your Jobber Handles
DART UNIONS



ALL DART UNIONS
HAVE A
Bronze to Bronze Ball Shaped Joint

Because of this feature, the Dart cannot deteriorate at the vital part, and is easily connected whether pipes are in or out of line.

MANUFACTURED BY
DART UNION CO., LTD.
TORONTO

A furnace is no better that its poorest joint

A RAGING blaze will find the joints between fine fire brick or poor fire brick with equal certainty; so a brick furnace of the best refractory is like a strong chain with one weak link. There is one furnace lining that always presents its full strength to the inferno of the furnace—

PLIBRICO JOINTLESS
FURNACE LINING

Plibrico is a superior refractory in the handiest form—unbaked, so that it may be molded and pounded into any required shape to suit any possible furnace requirement. It is then baked or vitrified in place, forming a rock-like, gas-tight, and, above all, a jointless refractory lining, resistant to temperatures ranging to 3100 F. Its form makes it universally adaptable; its quality makes it best for every purpose.

Plibrico is delivered only in steel containers of distinctive appearance as shown below. This container identifies the genuine Plibrico and keeps it in perfect condition.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

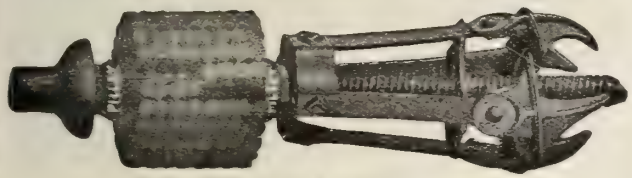
HINTS TO BUYERS

The Simplest and best cleaner on the market is



PILLEY'S

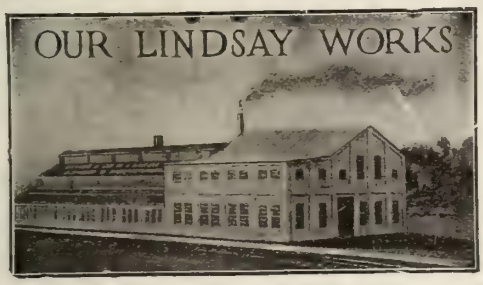
Combination Flue Brush and Scraper.
Guaranteed not to break or the wires to pull out or lay over. A simple turn of the hand adjusts it to the tube, and the brush removes what the scraper loosens.
For sale by leading Canadian jobbers.
Manufactured by
PILLEY PACKING AND FLUE BRUSH MFG. CO.
623 South Third Street - - - St. Louis, Mo
Eastern Office: 71 Fulton St., New York.

One Ton or a Shovelful?

One man can raise a ton with the **Godfrey Conveyor** and not exert a fraction of the energy required to lift a shovelful of coal. He unloads a carload in 1½ hours at an average power and labor cost of from 5c to 7c per ton. When you realize that this equipment costs no more than a good truck, you will want to know more about it. Ask for Catalog D.

Godfrey Conveyor Company
Elkhart, Indiana, U.S.A.

Water Turbines, Hydraulic Governors Centrifugal Pumps



Boving Hydraulic & Engineering Co., Limited

"Pop Off" Steam Carries Ashes Away

"Into the hole and away they go" describes ash removal with a Green Steam Jet System. At the Kewanee Boiler Co., they use "Pop off" waste steam to do the work.

Write to Dept. X for descriptive literature.

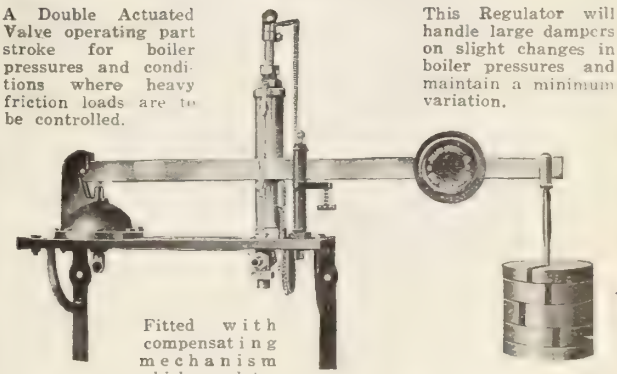
D'ESTE

Hydraulic Damper Regulator

A Double Actuated Valve operating part stroke for boiler pressures and conditions where heavy friction loads are to be controlled.

This Regulator will handle large dampers on slight changes in boiler pressures and maintain a minimum variation.



Fitted with compensating mechanism which regulates opening and closing.

Our Catalogue No. 50 of CURTIS ENGINEERING SPECIALTIES sent on application.

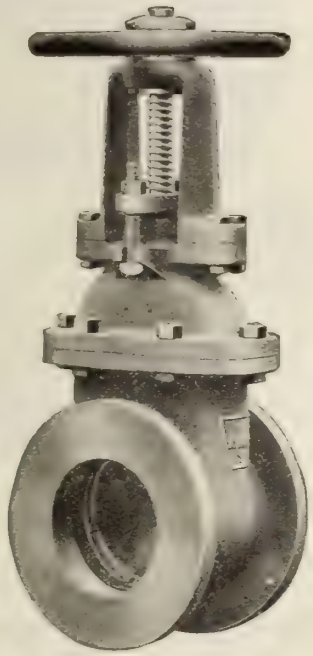
KERR



Valves of Quality

OUR long experience, together with the exercise of the greatest care with a view of designing the most modern and approved goods, is reflected in the satisfactory service given generally by KERR Valves.

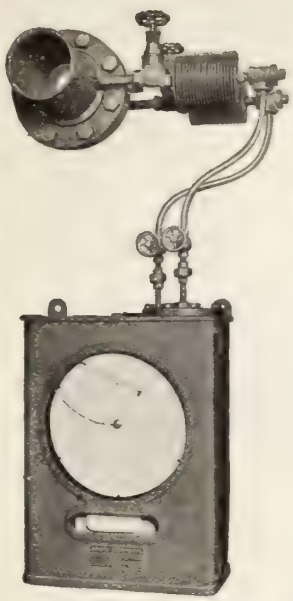
In many cases KERR Valves have been adopted as standard equipment by engineers who appreciate the value of our guarantee—a guarantee based on the most rigid tests before the valves are shipped.

MADE IN CANADA

The Kerr Engine Co., Ltd.

Valve and Hydrant Manufacturers
Walkerville, Ont.

BAILEY Fluid Meters



Unless you know exactly how much steam you are using to heat your plant—unless you are able to keep comparative records—how can you know how near to the standard of practical operating efficiency your daily steam consumption approaches?

The Bailey Fluid Meter will give you all the information required for this check. It will indicate—and record for future reference — record and integrate Steam Flow, high or low pressure, with accuracy and with practically no attention.

The Bailey Fluid Meter is self-contained, portable and is made with capacity to suit each particular installation. It records rate of flow in any desired units on 12-inch, 24-hour, uniformly graduated charts. IT WILL SAVE ENOUGH IN A SHORT TIME TO PAY THE COST OF INSTALLATION.

BAILEY Multi-Pointer Gauges

Can be equipped with separate pointers to indicate scale readings of practically every factor of operation. Each pointer has a 10-inch motion over illuminated scale, graduated so that readings can be made at a distance of 20 feet.

All Bailey Products are made in Canada

Bailey Meter Company Limited
177 Delorimier Ave., Montreal, Que.

MAGNOLIA ANTI-FRICTION METAL

is always uniform in composition and dependable in service. It adapts itself quickly to rough or scored shafting, makes smooth highly polished contact surfaces and "sets" particles of grit where they cannot cut the journal or appreciably increase friction.

Magnolia Metal melts and pours well, is easily peened and scraped in and is perfectly adapted to a very wide range of speeds and pressures. With the lowest frictional coefficient of any known bearing metal, it runs cool with less lubricant and is excellent protection against hot boxes and melting out where lubrication is neglected.

Sold in ingots and cored bars, the latter to eliminate shrinkage, and pattern and casting costs on small bearings.

Write for test data.

THE ANDERSON MODEL "D" STEAM TRAP

Ensures Live Dry Hot Steam

In order to obtain the highest efficiency from each square foot of heating surface in your plant, it is necessary to deliver live, hot, dry steam to the different steam apparatus and keep it dry by removing the condensation as fast as it accumulates.

The sturdy, simple construction of the ANDERSON, together with the ease with which it can be changed to accommodate varying pressures, makes it the logical steam trap for this work.

Wherever installed it has given perfect service uninterrupted by breakdowns or adjustments.

Let us send you a catalogue.

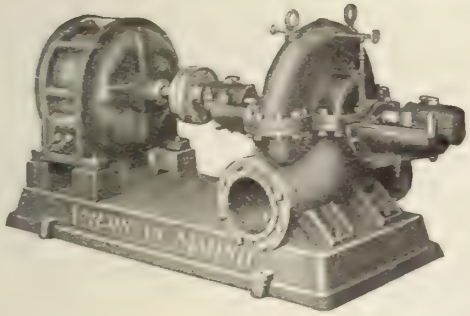
AMERICAN-MARSH PUMPS
Centrifugal and Direct Acting



Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The Line includes :

Boiler Feed Pumps	Jet Condensers
Air Compressors	Vacuum Pumps
Deep Well Engines	Condensation Pumps
Centrifugal Pumps	Sump Pumps

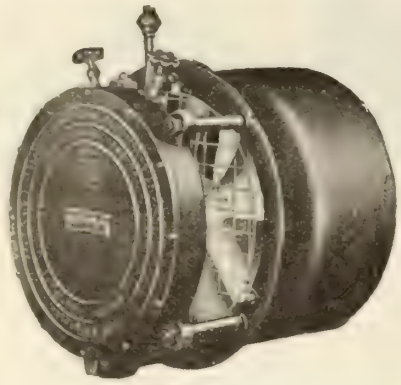
TURBO BLOWER



Solve the Coal Shortage Problem

YOU can adopt no more effective means to meet fuel shortage than by installing Coppus Turbo Blowers. They make it possible to burn low grade fuel with satisfactory results. Because of this and many other economies effected by their use many of Canada's largest plants have adopted Coppus equipment. To wit:

T. Eaton Co., Hamilton; **Farmers' Dairy Co.**, Toronto and Napanee; **Simpson Knitting Co.**, Toronto; **Canada Foundries & Forgings**, Welland and Brockville; **Can. National Rys.**, Leaside; **St. Michael's Hospital**, Toronto; **Municipal Abattoir**, Toronto; **Goodyear Tire & Rubber Co.**, Bowmanville; **Davis Leather Co.**, Newmarket, and several other firms.

Investigate Coppus Blowers now--full information promptly furnished.

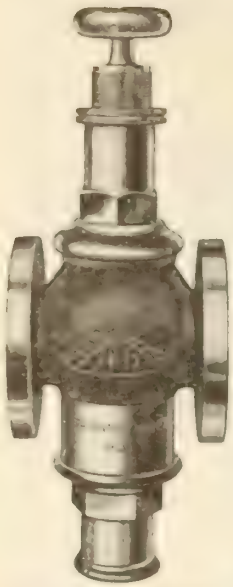
MORRISON

Pressure Reducing Valves

Efficient — Reliable

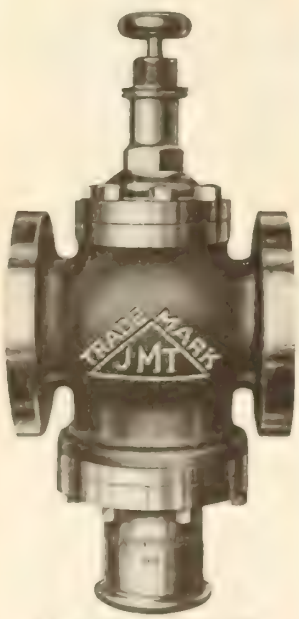


J.M.T. Flanged Reducing Valve

Non-Equalizing

Extremely Sensitive

J.M.T. Reducing Valve, differential type, iron body.

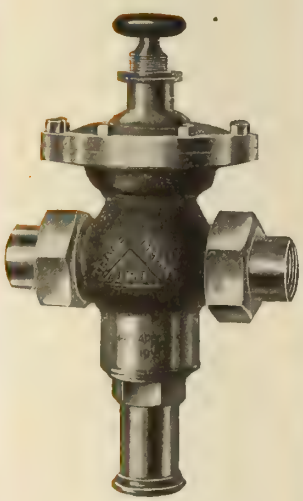


J.M.T. Reducing Valve—Iron Body Bronze Mounted.

Nothing could be more positive than the action of the J.M.T. Pressure Reducing Valve in which the low pressure is controlled by the low pressure steam. When the desired low pressure has been obtained the low pressure steam closes the valve. Its simple, automatic effectiveness is the result of years of experiment.

J.M.T. Reducing Valves are made to suit every requirement and are sold with the well-known Morrison guarantee.

"Every Installation is a Demonstration of Merit"



J.M.T. Reducing Valve—Low Pressure.

For reduced pressures under 5 lbs. per sq. inch. The large diaphragm provides ample power to operate the valve on very low pressures and make the valve sensitive to the slightest change in the reduced pressure.

Valve Satisfaction For You

In every industry and in many of the largest plants in the country Mueller Valves have supplanted inferior makes. The Mueller is a standard valve with many special features.

Mueller Valves are positive in action and are so designed that the stem threads are protected by valve bonnet when it is open. The inside threaded bonnet gives added strength to the body and a positive wrench grip when removal is necessary.

MUELLER

Globe, Angle and Check Valves

have a special packing composed of copper strands with a lead core embedded in flax and graphite to resist high pressure. The body of the valve is the newest type barrel shape — the strongest design. These valves have been tested by Provincial authorities and registered for 175 lbs. working pressure. Let us send you a sample from stock.

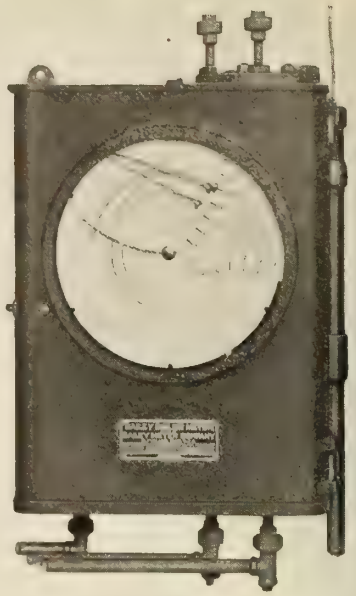
Top-Heavy Coal Bills

can only mean
Leaks in the Boiler Room

There is only one way to remedy the trouble, that is to make a study of the individual performance of each boiler.

THE BAILEY BOILER METER

is the logical medium for this work. Among other things, it will show, and chart for permanent reference, exactly what the operating conditions are at every instant—it will show just where the losses, if any, occur—and why. Moreover, it tells your firemen, simply and clearly, just what attention the fires need to get the maximum power with a minimum consumption of fuel.

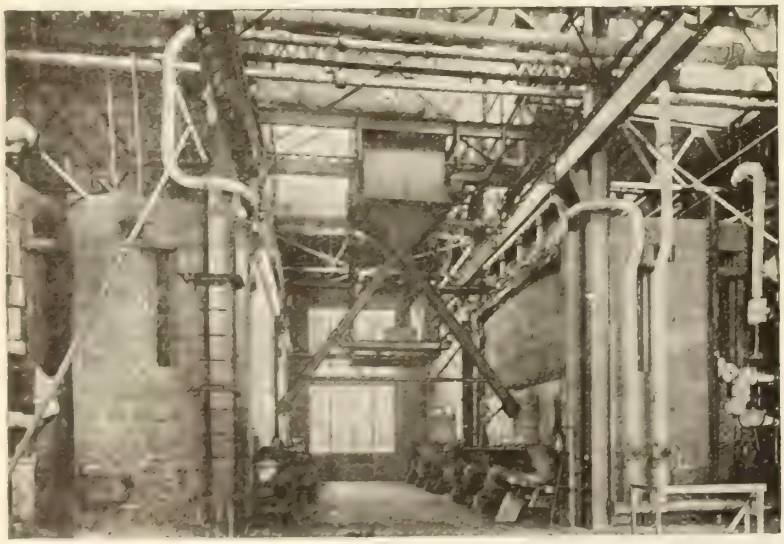


Made in Canada.

Bailey Meter Company Limited

177 Delorimier Avenue, Montreal, Quebec

Heat Costs Money—Why Waste It?



These four 1050 h.p. boilers in the power plant of the Dominion Power & Transmission Company, Hamilton, Ontario, are insulated with 45,000 Nonpareil Brick placed in the setting walls and over the steam drums.

Heat losses by conduction, radiation, etc., have for years been common to all power house plants. They have, in fact, been accepted as a sort of necessary evil.

Where comparatively high temperatures are employed the insulation material must be more than merely a good non-conductor. Fusing, shrinkage, convenience, structural strength, etc., are factors that must be considered.

NONPAREIL INSULATING BRICK

has, by actual experience, met these exacting requirements to a remarkable degree. It forms a permanent, built-in insulation; unaffected by jars, vibrations or by expansion and contraction. As for efficiency, by actual tests it has reduced by about two-thirds the heat loss by conduction and radiation. The saving in fuel alone will repay the cost of installation in a year or less.

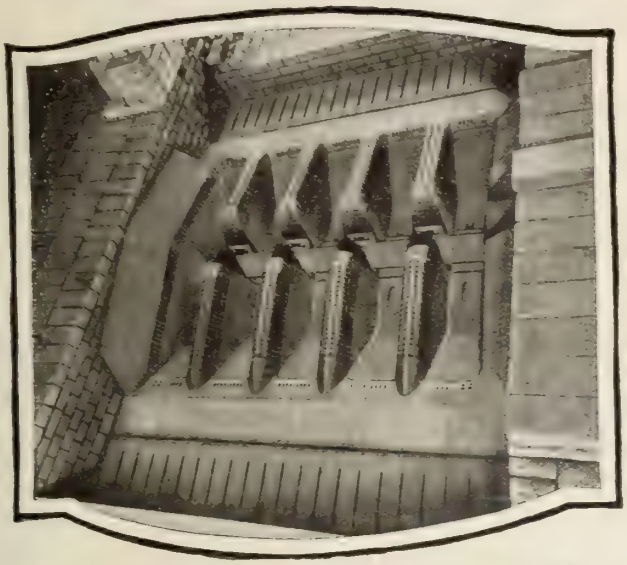
The uses and advantages of insulation in brick form, are explained in the 72-page book, "Nonpareil Insulating Brick," which is sent free on request. Write for it.

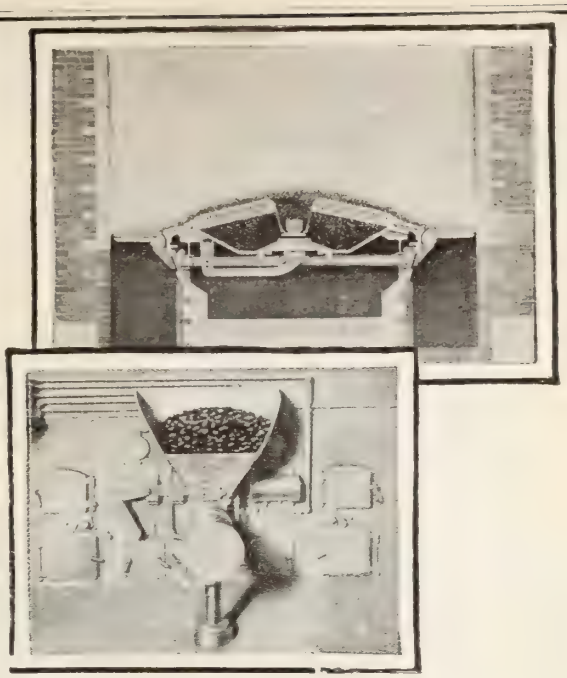
ARMSTRONG CORK & INSULATING CO., LIMITED

503 McGill Bldg., MONTREAL

11 Brant St., TORONTO

High duty stoking without high priced complications





Multiplying retorts without multiplying moving parts

MULTIPLE retort stokers are not "sold on price." So apparent is the fuel economy of multiple retort stoking that stokers of this type have often been installed where special conditions made their installation cost much greater than the expense of other types of stokers. The greater first cost and installation expense have been justified by operating economies—but it is no longer necessary.

A new principle—the *"lateral retort"* construction—has made possible a *multiple retort effect in a side-cleaning stoker*. All the advantages of multiple retort stoking—high efficiency, flexibility and overload capacity—are found in the *"lateral retort"* stoker. Yet it is practically as simple and therefore as economically maintained as a side-cleaning stoker.

The views above illustrate the ingenious construction that makes greater economies possible. Coal is underfed to the central retort by successive strokes of a steam driven ram and pusher blocks. It is then *underfed* to the several lateral retorts by pusher rods and blocks operated by an ordinary steam cylinder. Throughout its travel the coal is underfed. At no time is it overfed onto side grates as in other side-cleaning stokers. Consequently the *"lateral retort"* stoker is the only entirely underfeed side-cleaning stoker yet devised.

Note the many advantages of the *"lateral retort"* principle explained opposite. These betterments are fully described in a new bulletin.

Advantages of the *"lateral retort"* principle

1. **Coal is underfed throughout**—not overfed onto side grates. This is the only truly **underfeed** side-cleaning stoker.
2. **One simple moving unit for five or more retorts**—The feeding mechanism of the lateral retorts is controlled independently of main feed, permitting ideal fuel distribution under all conditions.
3. **Simplest cleaning mechanism**—a perfectly balanced dump plate easily operated by hand.
4. **No need for basement ash pits**—A trench 6 to 18 inches below the floor line is sufficient excavation for ash pits. This greatly reduces installation cost and makes the stoker adaptable to boilers already in service.
5. **Plate tuyeres**—reduce siftings and lower replacement cost.
6. **High air cooled front and rear tuyere blocks**—keep fire and clinkers away from front wall and bridge wall, reducing furnace maintenance.

The Safe and Certain Boiler Cleanser

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.**

BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.

Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

Dominion Belting Company, Limited

Hamilton, Canada

Sole Manufacturers of the celebrated "MAPLE LEAF" Brand Stitched Cotton Duck Belting and Belt Dressing.

The demand for our products has steadily increased because the standard of quality has been maintained.

We make only one grade, the best that can be produced.

"MAPLE LEAF" is the strongest, truest running, most economical and efficient belt on the market for transmission of power, conveying, etc.

Being thoroughly waterproof it is suitable for running in wet or dry places. **"MAPLE LEAF"** Belt Dressing is different to others offered in that it is equally good for all kinds of belting, leather, rubber, or Balata, as well as our own make.

Write us for prices, and if desired we will be pleased to furnish samples and further information.

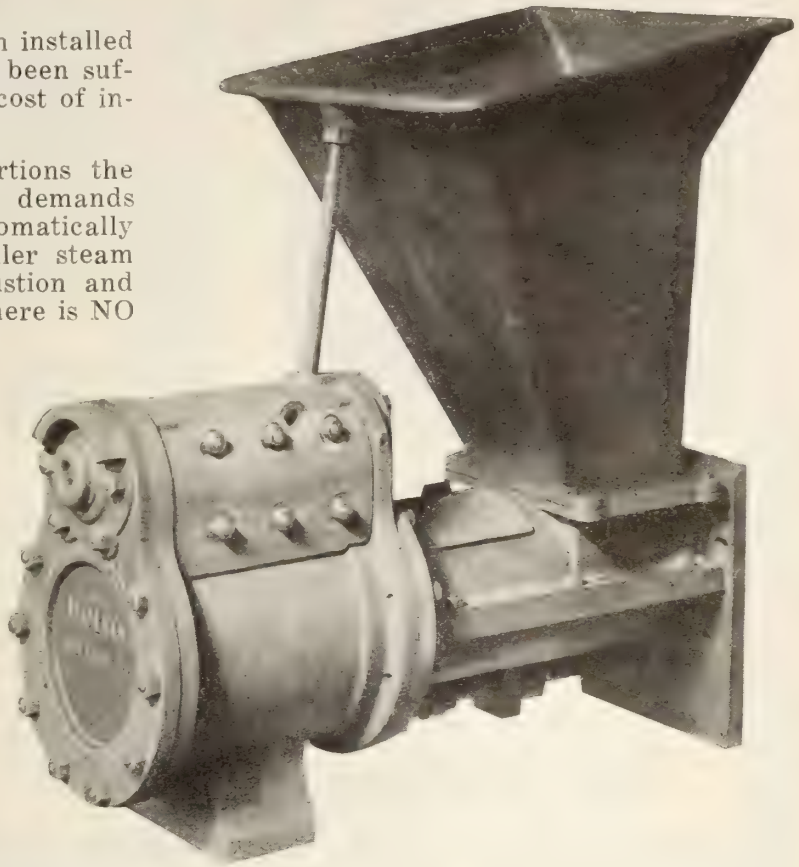
A trial order will convince you of their utility

DOMINION BELTING CO., Ltd., Hamilton, Canada - **Quebec Branch: 51 Duluth Bldg., Montreal**

MACLEAN STOKERS

Wherever the MACLEAN STOKER has been installed the saving in both fuel and labor costs has been sufficient, in a very short time, to pay for the cost of installation.

The MACLEAN STOKER correctly proportions the coal feed and air supply to meet varying demands upon the boilers. These quantities are automatically controlled through the medium of the boiler steam pressure itself. It assures complete combustion and no matter what grade of soft coal is used there is NO SMOKE .



THE COAL IT SAVES
SOON PAYS ITS COST

Let us estimate the saving to be made in your plant

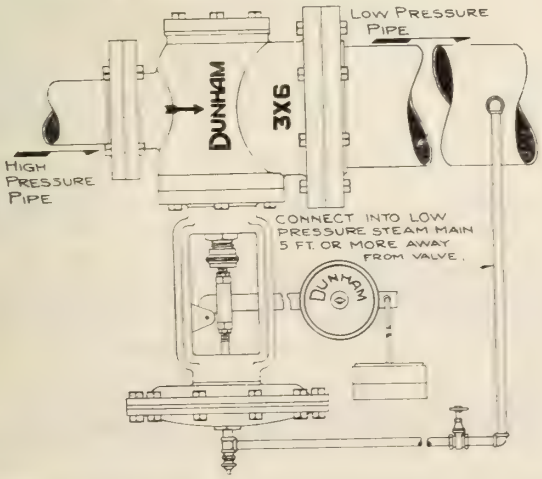
The DUNHAM HEATING SERVICE

REG. TRADE-MARK

(Made in Canada)

Reducing Pressure Valves

The Dunham Expanded Outlet Reducing Valve shown installed in horizontal steam main is especially designed for steam heating systems which require very low pressure. The expanded outlet permits quick steam expansion and facilitates reduction from high initial pressure to as low as atmospheric pressure.



Varying High Pressures Automatically Reduced to Constant Low Pressure

Dunham Reducing Pressure Valves insure an unvarying pressure on the low pressure side of the valves despite a considerable variation in pressures on the high pressure side. Steam, water or air is reduced to the desired pressure (atmosphere minimum) in one step without chattering.

Dunham Reducing Pressure Valves are applicable to a wide range of pressure service. An interchangeability of diaphragms which is permitted by standardized construction takes care of almost any pressure requirement.

Made in Straight and Expanded Outlet patterns. Finest materials and workmanship. Complete data on request.

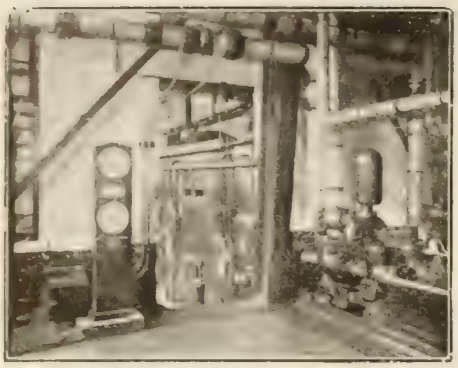
What is Going On In Your Boiler Plant?



With fuel both scarce and costly, this is the question many an owner is asking his Chief Engineer. It is an important business which is carried on in the boiler plant and must be given serious attention. Accurate information of the evaporation of water for the amount of fuel burned each day is essential.

The VENTURI Meter

"VENTURI" Registered.

is furnishing this information in thousands of boiler plants. Over twenty years of service has proved the Venturi to be supreme for boiler feed measurement. It has long since been accepted as the **Standard Meter** for the boiler room.

Bulletins 93 and 197 give details.

DE LAVAL
PUMPING EQUIPMENT AT HAMILTON, ONT.

IN 1917 specifications were issued by the City of Hamilton, Ont., for a 10,000,000 gal. steam turbine driven centrifugal pumping unit and a 10,000,000 gal. electrically driven centrifugal pump, and contracts were ultimately signed for a De Laval geared steam turbine driven two stage centrifugal pump and a De Laval 10,000,000 gal. per day centrifugal pump driven by electric motor.

The motor driven pump, when tested, Feb. 5, 1920, delivered 10,028,571 Imperial gal. per 24 hours, against a total head of 299.92 ft. with a combined efficiency, including pump and motor, of 75.98% and a pump efficiency of 80.4%. The guaranteed pump efficiency was 77%.

The steam turbine driven pump, when tested on Oct. 30, 1920, was found to deliver 11,110,000 Imperial gal. per 24 hours, against a total head of 310.4 ft., using steam at 169.7 lbs. gauge pressure. Reduced to standard steam conditions, this amounted to 117,000,000 ft. lbs. per 1,000 lbs. of dry steam, without giving credit to the unit for the heat returned to the boilers by vacuum and boiler feed pump exhaust to an open heater. The guaranteed duty was exceeded by 2.8 M.F.P.

The steam turbine driven centrifugal pump is not only practically equal in overall efficiency to the best reciprocating pumping engines, but costs much less for buildings and foundations and is less expensive for attendance and upkeep, including repairs and lubrication. It represents the most economical method of handling water.

Our engineers will be glad to study your conditions and to submit estimates.

Cutting Corners

Coal costs are sky-rocketing. Rigorous coal economy is absolutely essential—this year more than ever.

Steam must be carefully handled—all possible value must be utilized.

Equip your plant with

FISHER
PRESSURE REGULATOR
(Series 90)

And you have gone far to accomplish that desired goal—steam efficiency.

Use this valve wherever you desire an accurately gauged supply of reduced steam pressure. Fisher Pressure Regulator is noted for its reliability—long-lasting accuracy.

It also shuts off absolutely tight when low pressure consumption is stopped. Pressure will not build up on low pressure side.

The ever-increasing popularity of Fisher Specialties is gained through their excellence. A well-knit organization of happy workmen puts forth its best efforts to make each Fisher Specialty mechanically perfect. They are experts in their work.

Write for interesting literature about the Fisher Pressure Regulator. It is yours—with our compliments.

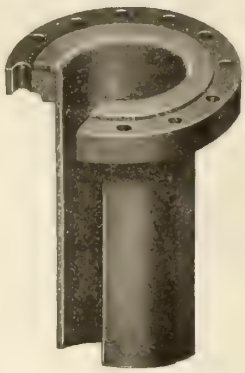
P⊕H FLANGED PIPE JOINTS

SCREWED



P.H. LAP

SCREWED FLANGES.—For general service, our screwed-on flange gives universal satisfaction and is the least expensive. For steam and water lines, at pressures up to 125 lbs., the flange is screwed home and not refaced. For higher pressure, we recommend screwing on the flange until the end of the pipe projects beyond the face, then refacing by taking a cut across the flange and end of pipe, insuring a perfect joint with the gasket bearing on the end of the pipe. This prevents the pressure from working through the thread of the flange, and insures a long life for the joint.

For all High Pressure service, and where it is objectionable to reduce the thickness of the wall of the pipe by threading, we recommend P⊕H Lap Joint.

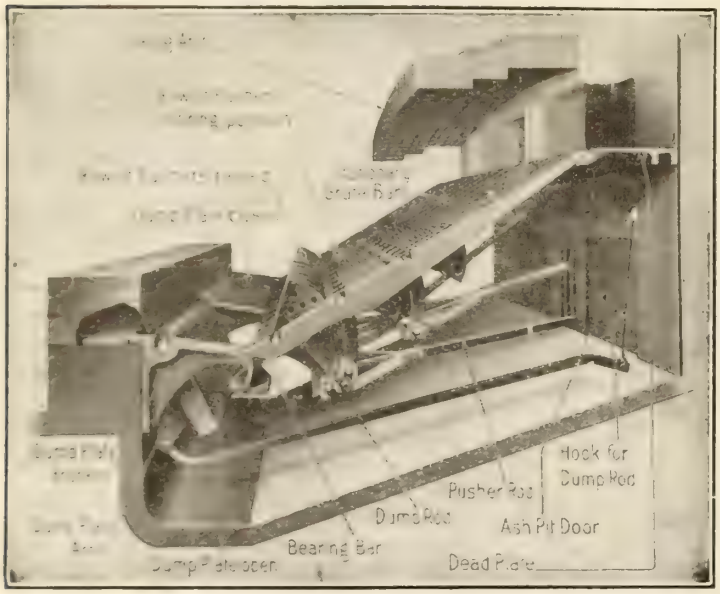
You need the National Hand Fired Stoker



Get away from inefficient hand stoking—without going in for costly mechanical stokers—come in between with the National Hand Fired Stoker which any "green" furnace man can be quickly taught to understand. Pusher rods at front of furnace operate successive banks of Pusher Grates, keeping the fuel moving downward—finally to the Dump Grates. Ensure proper progressive combustion. Any type of fuel—even waste—can be used. No smoke. No fuel in combustion chamber. No ashes in flues. Increased boiler capacity can be demonstrated. Can be installed under your present boilers.

National Hand Fired Stokers are made here in St. Catharines and sold at a very moderate price.

Engineering & Machine Works of Canada, Limited

ST. CATHARINES, ONT.

Eastern Sales Offices: Hall Machinery Co., Sherbrooke, and Birks Bldg., Montreal

Get the Most Out of Your Fuel

THE BOILER D. M. LIFE SAVER

Keeps your boiler clean and thus eliminates repair bills, besides reducing maintenance cost.

Will not injure boilers or fittings.

No acid—No chemicals—Just "D. M."

"D.M." Boiler Compound is a Vegetable composition, absolutely harmless, and will keep your boilers clean right down to the bare metal. Prevents all scale formation, corrosion and pitting. "D.M." Boiler Compound is used by many of the largest users of steam throughout the world including the British Government.

Manufactured by: HOUSEMAN & THOMPSON, Ltd., Newcastle-on-Tyne, England.

Sole Distributor for Canada :

POWER SHOW-

at Grand Central Palace

New York City — December 7-13, 1922
(except Sunday)

THIS great Exposition opens immediately after the annual December meeting of the American Society of Mechanical Engineers and the American Society of Refrigerating Engineers. Thousands of prominent engineers from all parts of the country will visit it. Every member should make a point of seeing it before he leaves town.

He will find here the most complete exhibition of power equipment ever shown under one roof. The representatives of the most progressive manufacturers of power plant appliances will be on hand to show and demonstrate the features of their exhibits. It will be well worth while for every engineer to meet these men and view the latest developments in the power plant field.

Every facility for the convenience of visitors has been provided by the management, which is the same that directed the Chemical Expositions and others during the past years.

The N. A. S. E. have fixed the following days for its gatherings; Friday, Dec. 8th, New Jersey day. Saturday, Dec. 9th, New England States and Connecticut day. Monday, December 11th, Greater New York day. Come on this day if you can and any other day.

National Exposition of Power and Mechanical Engineering

Grand Central Palace, New York City

Room 1102

Is Accurate Temperature Regulation Vital to Your Product?

A single batch of spoiled material, or a single process gone wrong because of crude temperature regulation methods, often costs much more than the installation of a dependable, accurate temperature regulator.

The Sarco Temperature Regulator—because of its simplicity, its absolute certainty of temperature regulation, and its remarkable adaptability to various mechanical units—serves day in and day out, always maintaining a dogged grip on the **correct** temperature, within the range 32 deg F. and 300 deg. F.

Operated by the sure expansion and contraction of an extremely sensitive liquid, Sarco Regulators are instantly responsive to the slightest fluctuation in temperature. No electrical, compressed air, water, or other outside attachments required for its operation. It is entirely self-contained and self-operating.

A Sarco operates on gas, steam or hot water heat. Can be supplied to control temperature in most any kind of manufacturing process—including the most delicate. Also controls room temperature.

Write us about your particular problems of temperature control and our engineers will be glad to make recommendations for obtaining a better product, an increase in production, or lowering manufacturing costs.

Sarco Regulators are sent on 30 days' free trial to prove their adaptability. If not satisfactory the regulator may be returned and the trial costs you nothing. Booklet J-73 contains interesting information. Write for it.

Self-Promotion And Sales Promotion

Are you interested in any of these fields—power—metal working—marine? As a manufacturer, or purchasing agent, as a superintendent or foreman, as an ambitious mechanic or engineer?

Use These Publications

They will keep you strictly up-to-date in all branches of mechanical engineering. Edited by practical men. Cheerful, inviting, instructive, authoritative.

POWER HOUSE

Twice a month—$2.00 per year.
Serves the power plant engineer—Steam, Electric, Refrigeration, Hydraulic.

CANADIAN MACHINERY

Weekly—$4.00 per year.
Covers the metal working field—serving shop executives, purchasing agents and owners. First-class mechanical paper and market paper combined.

CANADIAN FOUNDRYMAN

Monthly—$2.00 per year.
A paper for the foundry owner, superintendent and foreman. Claimed by its readers to be unexcelled.

CANADIAN SHIPPING AND MARINE ENGINEERING NEWS

Monthly—$2.00 per year.
Interprets marine engineering in its broadest sense, serving the shipbuilders, navigation companies and their officers. (The Editor holds an extra first-class B.O.T. certificate).

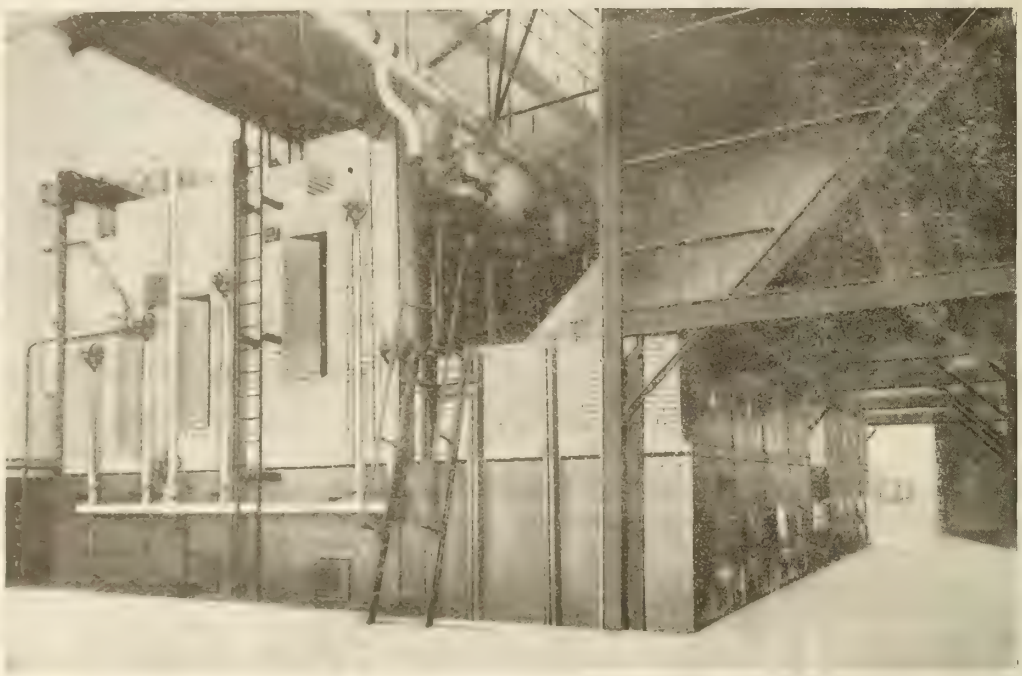
G & McC WATER TUBE BOILERS



Installation at Plant of the Match Co., Limited, Berthier, Que.

Greatly Superior to Ordinary Boilers

In substantiation of our claims in regard to Goldie & McCulloch Water Tube Boilers read the following communication from the Match Company, Limited, formerly Log Supply Company, Berthier, P.Q.:

The Goldie & McCulloch Co., Limited,
Galt, Ont.

Gentlemen: With reference to the four (4) 368 H. P. Water Tube Boilers, arranged in two batteries of two boilers each, which your Company erected in this plant in the summer of 1920, we are only too pleased to advise you that to date we have received excellent service from this equipment.

In the two years since the installation of these boilers we have never spent one dollar for repairs of any sort, as we have never had even a leaky tube to contend with and a statement such as the foregoing is the highest recommendation that we can make, both with regard to the quality of the material you used in constructing these boilers and also the care employed in their fabrication.

June 6, 1922.

Possibilities of the Power Plant Engineer

From the Starting Point of His Career to the Ultimate Goal an Engineer's Life is a Hard One, Mentally and Physically—Can it be Made More Worth While?

By T. H. FENNER, A.M.E.I.C.

EVERY man that starts a career as stationary engineer, does so with the idea that at some future time he will have a position which will give him a good living, the respect of the community in which he lives, and at least as much leisure as comes to the average citizen. We do not include, of course, those who take up work around a steam power plant as a means of filling in a gap when things in their own special line of endeavour are dull. These men as a matter of course fill the lower positions for a time, and then drift away. We have in mind chiefly the man who starts in as a young man, with the intention of rising to the position of chief engineer or mechanical superintendent of a large manufacturing industry, or perhaps a central power plant.

To such a man the stationary engineering or power plant engineering field presents much better opportunities to-day than it did a few years ago in Canada, but at the same time it demands considerably more from him. The earlier stages of the game are hard and exacting, and it is difficult perhaps to visualise the higher peaks attainable. It demands constant vigilance, attention to duty, and many hours spent in making up educational lapses when off duty.

The question which every young man must ask himself is, whether he has the capacity for sticking, enough liking for the business to make it attractive, and whether the ultimate reward is as great as he could obtain in any other line of endeavour. It may be granted off hand that it is only the exceptional man who does not realize that nothing is attained without hard work, but at the same time, no one wants to spend years of hard work in a field that is uncongenial and has nothing in the way of return to offer commensurate with the endeavor expended.

An Improved Status

There is no doubt but that the status of the power plant engineer is higher to-day than it has ever been, and it is beginning to be realised that the qualities required of the man in charge of the plant are just as high as the qualities demanded from any other manager of a department. The Governments of the various provinces are calling for a much higher technical standing than they ever did before, and that is naturally improving the class of man who is making stationary engineering his life work. Plants are more valuable, the ability of the engineer to operate them in an efficient manner is more important, and the tools given him to effect this operation are more costly in character, and their proper use demands skill and attention. On the other side of the case it has to be admitted that the factory manager, and owner, speaking generally, has not realised as he should all that is required from the engineer, and he has not made the position as attractive from a monetary standard as he might have done. That is a condition which will undoubtedly be remedied as time goes on, and the engineer begins to realise his true place in the industrial community.

The Engineer's Duties

The duties of an engineer in a modern manufacturing plant are many and various, ranging from the work of the man who fires a boiler and looks after a small engine, to that of the man who has a complicated plant containing a large variety of machinery and testing instruments, including electric generating apparatus, refrigerating machines, air compressors, and conveying machinery. One represents the lowest end of the scale, the other the highest, but there are many in between. Take for instance a large office building or institution where there may be no generating apparatus at all, but where the heating and ventilating equipment comprises a huge investment, and which must be run just exactly right if the tenants, who represent the revenue, are to be satisfied. The engineer in a building of this kind has not only to look after all this equipment, but in addition oversee the operation and maintenance of elevators, and not infrequently has to supervise the general maintenance of the building, such as painting, carpentering, roofing, and plumbing. This represents another point on the scale of an engineer's duties. The modern hotel is a good instance of the all round ability a man has to display who has charge of the mechanical end of it, for there is practically every kind of apparatus known to steam engineering science included in the power plant of such a building.

The road a man has to tread before he can hope to be in charge of any such plants as we have spoken of is a hard one. Let us see briefly what he has to face from the time he starts in as a fireman or oiler in any kind of a plant, until the day when he is put in charge of a real big installation, and has the opportunity to prove that his previous years have been well spent.

There are and always will be a large number of men who start in as firemen, and will remain as firemen all their lives, because human nature is so constituted, and two men starting equally at the bottom of the ladder will have very different rates of progress, depending on their temperament and ability. We say temperament and ability, because it often happens that a man with considerable ability is handicapped by a temperament or outlook on life, which continually prevents him from realizing on the capabilities that are in him. However we are taking the case of a man that means to rise, but knows well that there is no royal road to advancement, but merely a highway strewn with many obstacles, that have to be surmounted slowly and sometimes painfully. We do not consider here the man with a University education, because it is not usual for him to adopt stationary engineering for a profession, although he may go into stationary plants for a while to gain that practical experience which is necessary for him to properly apply his knowledge. Our hypothetical engineer will then spend some months at the laborious work of firing a steam boiler, cleaning fires as a matter of course, spending Sundays occasionally inside of the boiler when its cleaning time comes around, and making himself generally useful.

He can be absorbing a lot of practical knowledge about boiler operation during this time and, if he is of the right sort, he will be continually asking questions of the chief or second, or the boiler room foreman if the plant is a large one. His probationary time as a fireman may spread into one or two years, according as opportunity arises. After he once becomes thoroughly acquainted with the manner of handling the job he is in, and has more than a nodding acquaintance with the various apparatus in the boiler room, he will begin to look for advancement in the plant he is working in, and failing that he will look for a job in another and larger plant. Before he gives up the boiler room completely he should try and gain some experience with the handling of some of the mechanical stokers that are on the market. If at the time he starts in at firing his educational equipment is not good, he should start right in to improve it in his spare moments, realising that without a fair equipment mathematically he cannot go very far. There is to-day quite a number of places where he can get this education, either by personal tuition, or by correspondence. If he has the ordinary high school education he can start right in on his engineering education, either in technical school, or by correspondence, or merely by reading good engineering books. Always he must ask questions, even to the extent of making himself a nuisance. He will on occasion be steered wrong, but a man with his eyes open and a real desire to learn will not be very often misled. There are those who will try and mislead him, but they are the exceptions.

His next step will be to get into an engine room. Here of course as always he will have to take whatever opportunities arise, but he should try and get into as large a plant as possible, no matter in how lowly a position he may have to start. If he gets in as an oiler, he will have an opportunity of seeing just how the daily work is carried on, and also the privilege of helping the engineer or engineers in overhauling the various machines which the plant contains. He will learn to pack a pump, renew valves, adjust pump valves, tighten up the bearings of engines, adjust lubricators, etc., all of which is necessary to his training, and can be acquired in no other way than by actual experience. The plant will no doubt contain generators, either direct or alternating current, and he will see these machines functioning, and his enquiring mind will start him wondering as to just what makes them perform the work they are doing. He will enquire, and get whatever knowledge is available from the men on the plant. In addition to this he will turn to his books, and having the practical application in his mind's eye, will be better able to follow and understand the printed word. He will contemplate the switchboard with a new interest and will not be content with knowing that a certain switch has to be thrown in under certain conditions, but will try to find out why. He will look on the maze of connections at the back of the board and at odd times will amuse and interest himself with tracing out the various wires and busbars and understanding their connection with the switches at the front of the board.

All this will take time, and we may imagine him as now having been some months in the plant, and getting charge of a shift on his own account. Now at last he will be beginning to realise what responsibility means. He may only have charge of the engine room, and another man have charge of the boiler room, or he may have both under his care. If the plant is one that runs in shifts we would advise our young engineer to try and get charge of the boiler room shift in preference to the engine room. It is the boiler room that demands most of a man when all is said and done, and it is the part of the plant where a man can show the results of his training in a more pointed way than he can in the engine room. His job will not merely be to keep steam, but to keep it with the least expenditure of coal. To do this he will have to understand furnace efficiency, and if the job is a mechanical-stokered one, he will have to thoroughly understand the type that is fitted, while if it is a hand fired plant, he will have to remember his own experiences as a fireman, and apply them to handling the boiler room crew.

This matter of handling men is the hardest thing in the world to learn. It is not born in a man, but is a thing that must be learned, if success in big positions is looked for. It requires firmness and tact, the ability to make a decision and stick to it, and at the same time a considerable degree of sympathy and allowance for the weaknesses of humanity. Every man cannot acquire it, but no man can achieve success without it.

Further Experience

After the job as charge man on a shift in the boiler room, a shift in the engine room should be taken on, if possible. Here the chief quality required will be unceasing vigilance, and an appreciation of what small changes in operating conditions can mean. The rod that does not look quite right must be carefully watched and the right remedy applied, while the mysterious click that develops somewhere else must be traced to its source, and either eliminated there and then, or reported upon in such a manner that it can be remedied when opportunity arises. It is not the writer's intention to try to define the actual duties of a man in such a position, but rather to lay out a course which should be followed if possible in order to turn out the finished engineer. It is understood that all this time the work of education is being carried on steadily and industriously, and the rising engineer is not only becoming familiar with operation, but is getting such a knowledge of the principles of the machines he is working that their operation becomes so much more interesting. It is, of course, realized that every man cannot get into plants where he will have these opportunities, but what is particularly to be impressed is this, that it is of no good staying in a job that is a blind alley after all has been learned that the job has to offer. Get a new job in a different type of plant if not a bigger one, but always remember that what is required is not only length of experience, but diversity of experience. There is so much apparatus connected with the modern power plant and so many different types of equipment that it is only by moving around from time to time that it is possible to become acquainted with a reasonable amount of it.

It may take from three to four years, or even five, depending on the success met with in obtaining the kind of jobs wanted before a man feels competent to take absolute charge of a medium-sized plant. From this time on, progress is a matter of making good. Success in the first plant taken charge of will give a good lever to use in applying for the position that is a little better, and success in the first important job will depend on the use that has been made of the years preceding this job.

The Finished Product

We have reviewed in a general way the progress of the engineer from the bottom of the ladder to a position on the higher rungs, and we have outlined some of the experience he has to go through to get there. We will suppose that he goes on getting charge of larger plants from time to time until he arrives at a position where he can count himself fairly successful. What will he be by then? He will be a man who understands very clearly the natural principles governing the application of heat to the generation of power, and to that extent will be a scientific man. He will, besides that, have a wide experience in the application of those principles to the demands of modern industry, including, in most cases, the application of heat to produce cold, or refrigerating practice. He will understand also the economical operation and maintenance of all the different machinery, from the coal conveyor to the switchboard, and the intelligent use of all the different testing instruments in use to ensure efficiency of operation. He will be a man with executive ability, and should really know enough about modern cost accounting to see that the cost department does not put down charges against his department that properly belong to others. He should also know enough about investment costs and fixed charges to be able to advise intelligently on the subject of new equipment, and the scrapping of obsolete apparatus in favor of modern.

This progress upward which we have sketched in so lightly will have taken anywhere from ten to twenty years, and, of course, there are many men who are longer than that at the business before

getting anything worth while, and there are also some others who never achieve anything but the most moderate positions. Granted that a man has achieved success as we measure it by ability and opportunity, the question is, what will he get for his years of working up? What is his financial status?

Rewards Not Commensurate

There can be no doubt that as things stand at present the salaries obtainable are, except in a few cases, not as good as they should be. We may say that the average wages that can be earned by an engineer in charge of a small plant do not much exceed $30 per week, while the man in charge of a large plant who is getting over $50 is an exception. In taking these figures we are speaking of averages, which, after all, is what should govern. We know of one or two cases where the master mechanic of a large building, having charge of not only the power plant but all the maintenance of the whole building, is receiving $300 per month. That is, after all, not too high when the responsibilities of the position are considered. As we have pointed out, a man is not fit for one of these positions until after many years of hard, laborious work both of the mind and the body, and work performed at all hours of the day and night, for long stretches at a time. In every case, after he gets chief of any kind of a plant, he is expected to be at the end of a telephone night and day, in case of emergency. His training is a hard one; his knowledge gathered over many years is, or should be, wide. The man on the business side of the house, who may not have anything like the ability the engineer possesses, is, nevertheless, doing work which is productive from the management's point of view. He, therefore, attains a high salary much earlier and with much less effort than does the engineer, and has an ultimate possibility of reward far exceeding that of the man on the mechanical end. This has always been true, and is not only true in mechanical engineering, or steam plant engineering, but in any other line of engineering. The answer would seem to be, don't be an engineer, be a business man.

What To Do

The remedy would seem to be, as in all these cases, in organization. Now the writer does not for one moment mean organization such as is given by unions. To the engineer the trade union is probably the worst thing that could happen, because nothing will tend to deaden his initiative and ambition so much as the tenets of unionism. The organization that is needed is organization along the lines of a professional engineering society, with definite standards of qualification for membership, and an ideal to aim at. The C. A. S. E., for instance, has been in existence for over thirty years, and has woefully failed to do anything at all worth while on those lines, and at the present moment is in a precarious position in some ways. There has been a lack somewhere, and while some say it has been the leadership that has failed, others say that the membership never took enough interest to make it go.

As we said at the beginning of this article, the qualities demanded in the engineer are getting higher all the time. The examinations for certificates are getting stiffer gradually, and will continue to do so year by year. A new generation of engineers is growing up. Now is the time to try and set them on a proper footing so that they can build from the ground up.

If a word of suggestion might be offered, it is this. The first aim of a society of stationary engineers should be quality and not quantity. There are enough men at the business at present with high abilities to form the nucleus of an organization that would grow to be something worth while. Give the men without these qualifications something to aim at so that they will know that when they are eligible for admission they are being admitted to something that will put a seal of ability on them.

From the point of view of material change there is this to say. When a plant owner calls in a consulting engineer, he does so reposing full confidence in the man he chooses, and this confidence arises from the fact that the consulting engineer has the endorsement of the professional engineering societies. The consultant fee is paid without a murmur, and it often represents for a few hours what would pay the operating man for a month. Now, the consultant is absolutely justified in the fee he charges because he is capitalizing his years of experience and education. Stationary engineering or power plant engineering, from the operating point of view, is becoming a more highly specialized business. It is strictly in the hands of the operating or plant engineers themselves to achieve eventually a status equal to that of the professional man in other branches of engineering. It will not be done in a short time, but it can be done. Will it?

AN INVENTION EXHIBITION

One of the features of the Universal Exposition of Inventions and Patents to be held in Grand Central Palace, New York City, February 17-22, 1923, will be to celebrate, each day of the Exposition, one of the world's great inventors or scientists.

In view of the great interest shown by foreign governments in the Exposition, the first day, Saturday, February 17th, will be "International Day." Then, the following week will open with Sunday as "Marconi Day" or "Radio Day;" Monday, "Steinmetz Day," in honor of Dr. Chas. P. Steinmetz, the electrical wizard, of the General Electric Co.; Tuesday, "Edison Day," in honor of Thomas A. Edison, America's great inventor; Wednesday, "Bell Day," in honor of the late Alexander Graham Bell, who made the modern telephone possible; and Thursday, "Westinghouse Day," in honor of the late George Westinghouse, inventor of the air brake and many other inventions that have made railroad travel safe; and founder of the Westinghouse Electric & Mfg. Co., also the Westinghouse Air Brake Co., Pittsburgh.

The object of this Exposition is to fulfill an important universal need, and it is intended to:

(a) Bring the capital of America and the inventive brain of the world together.

(b) Give all inventors full opportunity to show the public, the manufacturer, the merchant, the capitalist and financier, the possibilities for utility, business, trade and commerce that lie in their inventions.

Inventors whose devices may be adjudged to combine novelty and utility with commercial practicability, will be awarded, by qualified board, cash prizes, gold, silver and bronze medals and certificates of merit.

The Exposition will be a veritable "Clearing House of Ideas" through which the man of originality and ideas is brought in personal contact with the man in need of ideas and with the man of money.

The Exposition of Inventions and Patents will be a place where anyone with an idea; formula; process; labor-saving plan, device, etc.; improvement on machinery; new invention; a developed and patented specialty, or anything saleable can exhibit. This will enable the manufacturer who is looking for some sort of device which will lessen the labor and cost of producing his wares, or assist in the economic production of his raw material or its procural, or help to secure the economic manufacture of such raw material; or the capitalist who is searching for some clever device or process in which he can see the possibility of increasing some of his idle money, go and see what the man of ideas has to offer.

NEW BOOK

A most interesting book has been published by the Taylor Stoker Co., illustrating a number of the large central station power plants in which the Taylor stoker has been installed. There are fifty of these installations in the book, which is of large size, 11 x 13, and printed on excellent paper. The chief object of the book is to show the class of power plants into which the stokers have been introduced, and on two pages facing each other are illustrations of the oldest and newest stations containing these installations. The plant of Bay Sate Street Railway Co., at Quincy, Mass., was equipped with Taylor stokers in 1905, and these are still operating. The illustration on the opposite page shows the new Hell Gate Station of the United Electric Power Co., which represents the very latest in power station design. The Taylor Stoker Co. has offices in Montreal and Toronto.

Self-Contained Coal Dryer, Pulveriser and Blower

Cheap Grade of Coal Used to Advantage—Any Desired Rate of Delivery—Preliminary Drying Process Unnecessary—Complete Combustion—Small Proportion of Paraffin Used

CONSERVATION of fuels is perhaps a matter that will more vitally concern the next rather than the present generation, but it is one that ought to occupy a prominent place in our scientific and industrial research work to-day. Cheapness of production, however, is an important present-day problem and one to which we must bend our untiring energies if we are to maintain our prestige and position in the world's commerce. Not the least factor in the cost of production is the item of fuel costs. With individual plants consuming over a thousand tons of coal per week and others using hundreds of tons of oil, the cost of fuel must bulk very largely in the annual balance sheet.

Of the various fuels available, pulverised coal would seem to offer many advantages from the point of view of cheapness. In the United States pulverised coal as a fuel has received much consideration and it has been widely adopted in many large power house plants. At the River Rouge boiler plant of the Ford Motor Co. the four supposed largest boilers in the world are fired by pulverised coal and blast furnace gas. This method of firing was only adopted after an exhaustive survey of all possible types and it would seem to indicate that there are potentialities in powdered coal that will well repay the careful consideration of fuel users.

In the cement industry it has been standard practice for many (about 60) years for firing rotary kilns. Whatever may be the impression regarding this fuel for other applications, such as boiler houses and furnaces, there can be no two opinions on its superiority for cement work.

In the utilization of powdered coal as a fuel there have been in the past both advantages and disadvantages. Among the latter were the costliness of the pulverising plant, the inadvisability of storing the powdered product for use, and difficulty in dealing with the ash. If these can be eliminated or at any rate considerably depreciated, there would seem to be a wonderful future for powdered coal. The advantages it claims are cheapness of fuel, extraction of most of the heating value, low labor costs, and the fact that low grade coal can give good results.

In the past a powdered fuel plant has not only been costly to install but equally costly to maintain and run, entailing, as it does, a coal dryer, with its auxiliary furnace, a tube mill or other pulveriser, elevators, conveyors, separators, bins and bunkers for storage, fans, etc. With the new invention named the Atritor all the disadvantages mentioned above are said to be eliminated. This machine dries, granulates, pulverises to any degree of fineness and delivers the fuel into the combustion chamber all in one continuous process as and when wanted, at any desired rate of delivery without any auxiliary plant whatever other than a feeding arrangement for the coal.

The first Atritor was put into commission about 12 months ago. During the intervening period this machine and two others have been subjected to very rigorous tests in the course of much experimental work. The machine as designed is known as the No. 10 size and it is guaranteed to give, with an actual power consumption of 30 h. p. an output of 1,800 lbs. of coal per hour pulverised from ¾-in. lumps to a fineness such that 95 per cent. will pass through a 100 x 100 mesh screen. A larger machine is also in contemplation.

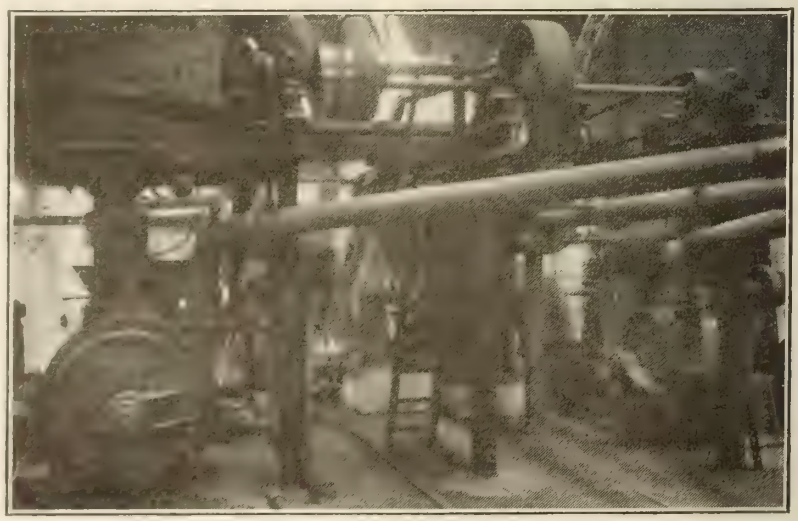
A typical Atritor installation as applied to two 140 ft. x 8 ft. rotary cement kilns is shown in the illustrations herewith and consists of two Atritors driven by 40 h. p. electric motors, each with a 10-ton raw coal hopper for feeding and an elevator for keeping the hoppers full, with a screw container from the elevator to one hopper. It is recommended that 40 h. p. motors be installed for driving this size of machine, though it will give full output when grinding coal not exceeding ¾ in. in any direction at 30 h. p.

An installation similar to that shown is capable of burning over 800 tons of cement per week. It is, however, advisable to have a third Atritor as a standby in case of breakdown through any cause. It is a simple matter to arrange the delivery pipes with flap valves so that any of the machines can deliver its product at the piont desired. The cost of pulverising coal by the Atritor system at Stockton is about 62c per ton, while by the old installation it was about $1.25 per ton.

Another decided advantage of the Atritor system of burning the fuel immediately is the fact that a lower grade of coal can be used with consequent decreases in cost. With the old type of plant a large part of the volatile combustible matter in the coal is lost during the drying operations and storage. The approximate difference between the lowest grade coal it was possible to utilize by the old system and the coal which can be burned quite satisfactorily by the Atritor system is about $2 per ton delivered at the works. The total costs for fuel burnt in the kiln, that is delivered at the works, handled and pulverised and propelled into the kiln are, therefore, $2.65 per ton by the old installation against $2.40 per ton by the Atritor.

The advantages of the Atritor system for pulverising coal may be summed up as follows:—

1. It is a small, self-contained unit for drying, pulverising and propelling the fuel direct into the combustion chamber ready for burning, in one continuous process.
2. It will deliver any quantity at any rate desired as and when wanted up to its capacity of 1,800 lb. per hour.
3. It is continuous in action and dis-



General installation of Atritor unit.

[illegible] Alfred Herbert, Ltd., who are the licensees and manufac-

penses with the necessity for storage bins.

4. It can be started and stopped at will.
5. The drying and pulverising go on together and the product is burned immediately without opportunity to absorb moisture after pulverisation. This is important as powdered coal is extremely hygroscopic.
6. The whole of the combustible contents of the coal pass into the furnace and are burned. There is no opportunity for the volatiles to be lost. This is a very important point as considerable waste of volatiles takes place during drying and storage under the old system.
7. It entirely supersedes the elaborate, expensive and dusty plant hitherto employed for the purpose.
8. There is no necessity for any subsidiary plant other than a feeding device for the raw coal.
9. The cost of the installation is low. The power consumed is low. The cost of maintenance is extremely low.

   The labor cost is low.
10. It is entirely dustless in operation.
11. The moisture contents of the coal make no difference to the working of the machine or to the resultant product.
12. The hot air supply for drying can be drawn from any convenient source of waste heat.
13. No smoke or soot is formed and no combustible matter left in the ash.
14. Pulverisation may be carried to any degree of fineness desired.
15. A high temperature can be obtained very quickly.
16. By the addition of a minute amount of paraffin (a patented process) (.07 per cent. by weight of coal pulverised) the time for heating up is reduced by 75 per cent. A rotary kiln is ready for use 40 minutes after lighting up.
17. The addition of paraffin also enables coal which is unburnable when ground by other means to be successfully burned by this system.
18. There is no heat wasted nor waste of fuel when damping down.
19. There are no screens used and therefore no clogging of material.
20. An efficient metal separator is incorporated in the inlet end of the machine. This dispenses with the use of a magnetic separator.

Layout of Atritor installation.

The addition of paraffin during pulverisation has produced such almost extraordinary effects that the process has been patented. The requisite amount for firing up is .07 per cent. by weight of fuel burned or about 1½ pints per hour to 1,800 lbs. of coal. The paraffin can be shut off when full heat is attained, or it can be kept on when pulverising very inferior coal in order to assist in maintaining the temperature.

The mechanical features of the Atritor consist generally of: (a) A hopper with variable screw feed driven by cone pulleys and worm gearing and level operated slide, for regulating the flow of raw coal. (b) A coal chute and metal separator in which any material of heavier specific gravity than coal is thrown out and thus prevented from injuring the machine. (c) Hot and cold air supply ducts. (d) A casing with fixed pegs of extremely hard metal in concentric rings on both sides. (e) A rotor disc with similar pegs on each side and rejector pegs on one side. (f) A suction and blower fan cased in a scroll. In the scroll are auxiliary air ports.

The coal feeds through the slide and screw and falls towards the centre of the machine where it is met by a strong current of cold air which is being drawn through an adjustable opening in the front of the machine. The air draught is adjusted to the amount of coal feed so that all the coal is pulled into the machine but anything heavier than coal rejected, falling down to the air inlet, thus dispensing entirely with the necessity for a magnetic separator. The pull of the fan and centrifugal force throw the coal through the intermeshing rings of pegs in the first disintegrating chamber, called the first effect.

The coal particles are then drawn by suction towards the centre again through the chamber known as the second effect. It will be noticed that the rings of pegs go completely across the first effect, so that the coal has no loophole to escape their smashing action. In the second effect, the rotating rings of pegs only go across half the chamber, leaving half the volume free except for stationary pegs. The innermost ring on rotor is composed. however, of pegs which go completely across the chamber and enter a recess in the casing on the other side. This ring acts as a rejector for coal particles that may be still too large for use. In addition a set of eddy currents are set up towards the centre on the side of the casing and towards the periphery up the side of the rotor disc. The circulation thus set up in the second effect completes the pulverisation until the particles of coal are so impalpable that they are drawn by the fan and propelled into the furnace.

For full capacity of 1,800 lbs. per hour with only 5 per cent. residue on 100 x 100 screen the slide under the hopper should be full open and the screw feed on the fastest rate. Hot air should be drawn in at a temperature of round about 450 deg. to 600 deg. C. At this temperature coal of a high moisture content will be completely dried in its passage through the machine. The auxiliary air ports in the casing on the delivery side should be shut. If for any purpose the required output is to be less than the above. the slide should be closed first and the cold air inlet regulated so that no coal is rejected by the metal separator. For a still smaller output the screw should feed at a slower rate and the slide worked in conjunction. The cold air will have to be adjusted until coal is not thrown out by the separator. This may necessitate the opening of the auxiliary air ports to give sufficient air for combustion.

A safe rule when using a hack saw is to maintain an even pressure and to keep blade cutting.

Some Elements of Economy in Air Compression

Steam Driven Air Compressors of Single and Compound Types —Electrically Driven Machines—Methods of Lubrication and Governing—Cooling by Water Jacket and Intercoolers—Types of Valves, etc.

By WM. CARTER, A.M., A.S.M.E.*
*Assistant General Sales Manager, Canadian Ingersoll Rand Co.

SECOND only to electricity in the extent and diversity of application, compressed air is one of the most important agents in every phase of the development of civilization. In the arts, sciences and manufactures, its use has wrought economies which could otherwise never have been realized. Compressed air appliances have exercised an influence upon improved standards of living, second to no other means of power transmission and application. Wherever properly applied, they have brought about economic results which are reflected in every field of activity. But the efficient application of compressed air presupposes an efficient source of compressed air. The most economical devices cannot work to advantage under a high cost of power.

The cost of compressed air, for whatever purpose or however produced, involves three separate items;—first, interest and depreciation on the investment for compressing equipment; second, cost of operation; third, cost of maintenance or up-keep. Extravagance in any one, will offset saving in the other two. Compressed air can be had at minimum cost only when each of these three items is minimized. All three depend fundamentally upon the design and construction of the air compressor.

An air compressor is a machine for transforming energy from one form to another, and is to be considered as primarily made up of three parts, namely, the driving element, the compressing element, and the mechanical structure, combining these two which may be designated as the power transmitting element. It is not always possible to draw the line sharply between these several elements, but the subdivision can be made with more or less exactness.

In the transformation of energy there is a certain loss. The measure of overall efficiency of an air compressor is the ratio of the horsepower applied as initial energy to the horse-power represented delivered. The inevitable losses in air compression may be broadly classed under five headings, as follows:

The first loss is that due to friction in the mechanical structure which transmits the power from the driving to the compressing element. The second loss is that arising from the heating of the air during admission to the cylinder, resulting in a reduction of its density and a diminished volumetric efficiency of the cylinder. The third loss arises from the heating produced by compression and its effect upon the air during compression, calling for more power. The fourth loss comes from the reduced volumetric efficiency of the cylinder due to the fact that the intake air is seldom at atmospheric pressure owing to friction in the inlet valves and passages. The fifth loss is also one of volumetric efficiency due to the effect of the clearance air in reducing the effective length of the admission stroke.

These various losses can be kept down to the minimum by correct design, and construction, but they can never be entirely eliminated. It is not possible even to give average percentages for any one of these losses, which may occur in different combinations, depending upon the mechanical details, the general type, the speed and the capacity of the compressor. After all these losses have been deducted the net efficiency of the machine remains, and of this Mr. Frank Richards says, "It is safe to say that the ultimate efficiency never goes as high as 80 per cent., while it often goes below 60 per cent."

Taking up now, in order, the three primary parts into which the compressor has been divided, the driving element comes first for consideration. Air compressors can be broadly defined as either steam driven or power driven.

The Steam Driven Machine

The ordinary steam driven compressor is simply a steam engine with one or more air cylinders directly coupled on an extended piston rod. With this understanding it will be unnecessary here to enter into any detailed consideration of the design of the steam end. What constitutes good steam engine practice is the best compressor practice so far as the steam end of the compressor is concerned.

However, there is one vital distinction between engine and compressor practice. The steam engine for ordinary power purposes must maintain a constant speed irrespective of load. The steam driven air compressor, on the contrary, in order to maintain its output of air properly adjusted to its load, must run at a variable speed, for its piston displacement or its capacity is directly proportional to its speed. This means that while the steam engine has a variable load per stroke, the air compressor has a constant load per stroke, except for the small discrepancy due to varying friction and compression efficiency at varying speeds.

This feature has no particular bearing upon the performance of air compressors with simple steam cylinders, but it has a most important bearing upon the application of compounded steam cylinders to compression work. The first essential of successful steam compounding is in maintaining the proper ratio of expansion. This means that for a given steam pressure, for a given back pressure and for a given cylinder ratio, there is one and only one proper point of cut-off for both steam cylinders.

In any given case the first and third conditions must be considered constant, leaving the second condition as the variable which is to be adjusted to meet varying conditions. Where a constant speed must be maintained regardless of load, this must be accomplished by change of cut-off; and in compounded steam cylinders this immediately destroys the proper ratios of compression, and sacrifices economy. Constant speed practice with compounded engines must be a compromise, even at the best.

But in the air compressor, where the load per stroke is constant, the cut-off on the steam cylinders remains practically constant, and the correct ratio of expansion is maintained over the full load range. The word "practically" is here used advisedly, since there is bound to be a very slight departure from perfect conditions to produce the necessary change of speed under varying loads. But it will be evident that the air compressor offers the ideal opportunity for securing in highest degree the advantages of steam compounding.

It would appear proper that in steam driven air compressors the first element of economy lies in using compounded steam cylinders, operating under pressure which will make the saving worth while. The peculiar operating conditions of the air compressor, just explained, justify compounded steam ends under pressures lower than would be advisable in ordinary engine practice. The largest builders of air compressors are recommending steam ends for as low as 80 pounds boiler pressure running condensing, and for 100 lbs. running non-condensing.

The three fundamental advantages of compounded steam cylinders on air compressors may be summarized as follows: Lower fuel consumption and fuel cost, lower cost of boiler feed water, lower cost of boiler plant and accessories.

In Canada, due to extensive Hydro electric developments, and electric pow-

er frequently becoming available after steam driven compressors are installed, a large Canadian builder has adopted the standard of building all of their steam driven compressors with the air compressing cylinders located next to the frame so that the machine is readily convertible to a belt driven machine when power other than steam is available.

Turning now to the subject of power driven compressors, they are in general an evolution from steam driven types. They differ, however, from the others in the vital fact that while steam driven compressors are variable speed machines, power-driven compressors are in the vast majority of cases constant speed machines. This makes the problem of regulation quite distinct in the two cases. This point will be taken up more fully later on.

Belt and Other Drives

Discussing now the various methods of drive, belt drive is the most common and is always applicable either from line shaft on smaller sizes or by individual driving element using either electric motor or oil engine belted to suitable belt wheel. A good rule to follow for belt centres is the diameter of the driven pulley plus 8 to 10 ft. Where long belt centres cannot be had the short belt drive referred to later can be applied.

Rope drive is perhaps the next choice, although it is seldom used where the power to be transmitted is small. It is particularly advantageous in large sizes where short centres only can be had, as the grip of the rope in the grooves gives the necessary pulling power without undue tension and bearing friction. The durability and efficiency of the rope drive depend entirely upon the shape of the rope grooves and upon the use of a suitable number of ropes so that no one rope is under excessive strain.

The use of tighteners for rope is always to be avoided. A recent development by one of the larger builders, however, opens up large possibilities for belt drive on close centres without any increased friction. This arrangement involves the use of a floating idler pulley and a very slack belt. The weight of the idler takes up the slack of the belt and increases the arc of contact on the driving and driven pulleys so that the full power is transmitted without any undue strain on the bearings or on the belt itself.

Gear drive and silent chain drive are never desirable and should be used only where the demand for compactness renders them imperative. The best practice places the limit of power for gear drive with a raw hide pinion at 40 h. p.; for gear drive with a steel pinion at 60 h. p.; and for silent chain or herringbone gear drive at 50 h. p.

A very modern development is the direct-connected electric driven air compressor with the rotor of a synchronous motor mounted directly on the compressor shaft. This construction is not applicable to smaller units than about 700 cu. ft., 100 lbs. pressure compressors, because the cost for D. C. synchronous motors of small power becomes excessive. On moderate and large-sized machines, however, this design affords the very highest possible economy in power driven compressors. Recent improvements in air valve movements and in air cylinders design which permit much higher piston speeds than ever before were considered practical, have contributed to the success of the direct-connected compressor unit of this design. Unless the valve and port areas are very large, the compression efficiency is so greatly reduced at the customary speeds as to offset the advantages of compactness. The choice of a direct-connected motor driven air compressor therefore, should be determined by an investigation as to whether the compressor had been specially designed for this method of drive.

The same general remarks apply to the direct-connected water wheel compressor. But as this style of drive is comparatively rare and can be used only where the head and volume of water are exactly right, this condition is not likely to come within the experience of the engineer.

The extensive use of compressed air for operating tools and other equipment by compressed air has created a demand for a new design of air compressors, that is, the portable type of machine, and the development of a complete line of these machines has been undertaken by a large builder. They can be gasoline engine driven, self propelled, for operating on standard gauge railway track or gasoline engine driven or motor driven portable units. In ranges of capacity these machines are available in 100, 150 and 200 cubic feet units.

The problems encountered in a steam cylinder of an air compressor are problems of expansion. Coming now to a discussion of the second element in the air compressor—the compressing element—we find here that the problems are those of compression, almost an exact reverse of those in the steam end. In compressing air all of the energy applied is converted into heat. At first glance, therefore, economical considerations would seems to indicate that this heat should be retained during compression. As a matter of fact, however, economical air compression depends primarily upon the thoroughness with which the heat of compression is removed as fast as it is produced. Compressor practice uses one or both of two methods for accomplishing this, namely, water-jacketing, and compounding or stage compression.

If the piston of a compressing cylinder could move so slowly that the water in the jacket could absorb and carry off all the heat, it is evident that this jacketing process would save all the work which is represented on the indicator diagram by the areas between the actual compression line and the isothermal curve. But in actual practice a compressor cannot be run so slowly, and water jacketing is only a partial solution of the cooling problem.

Temperatures increase with the pressure in the cylinder, and it is evident that the advancing piston steadily reduces the effective area of jacket. Near the end of the stroke, when pressure and temperature are highest, very little of the cylinder wall is exposed, and the greater part of the cooling area remaining in the cylinder head. This emphasizes the importance of head jacketing and the superiority of those constructions in which the air valves are not in the heads, thus affording the largest percentage of cool head areas.

But even under the best conditions, water jacketing realizes only a part of the saving which its theory promises. Some beneficial effect in this respect it certainly has, particularly in slow speed, long-stroke machines. But probably its greatest value lies in its effect upon the lubrication and the resultant wearing qualities of the machine. Compression at sea level and ordinary atmospheric temperature to only 75 lbs. gauge produces a temperature of about 400 degrees Fahr. If some means were not employed to reduce this temperature, the inevitable result would be the destruction of all ordinary lubricants and packings, and the rapid wear of piston rings, cylinders, rods and valves with extravagant leakage, loss of capacity, increased friction and excessive power consumption. But the water jacket keeps all parts reasonably cool and results in tight joints, free lubrication, little wear, reduced friction, easy running, and sustained capacity and efficiency.

Lubrication

It would seem advisable at this point to make some mention of the lubrication of air compressors as it has been found that not sufficient attention is given to this subject and the author will only touch on the subject briefly, and dealing only with the lubrication of the air cylinders of the air compressing element. For average normal conditions, the oil should be a medium bodied mineral of the highest quality, not compounded with fixed oils such as animal or vegetable, and should be carefully filtered in the final process of manufacture.

The quantity of lubricating oil to feed to the air cylinders of compressors cannot be stated in exact terms due to the varying viscosity of different oils, the heat of compression and the size of cylinder. It may be stated in general, however, that after the cylinders have acquired smooth and polished surfaces, the quantity should be reduced to the lowest limit to avoid the possibility of accumulation of carbon and sooty deposits within the system due to excessive use.

Cooling

It is perhaps unnecessary to say that it is almost as important that air should be admitted into the cylinder cool, as that it should be kept cool during com-

pressure. If a water jacket were not used, the entering air would be heated while passing through the hot valves and ports and by contact with the heated interior of the cylinder. This would mean the rarification of the intake air, reduced cylinder capacity, lower effeciency of [illegible] and excessive terminal temperature. Since jacketing is at the best [illegible] ally effective, this latter argument suggests the advantage of those constructions which admit air through one, or at least only a few, large openings where only the outer film of the air is heated rather than through a number of smaller openings through which the air is finely sub-divided and heated.

The second process of cooling—compression in stages—is analagous to an arrangement in which the compressing piston of a single cylinder is stopped at intervals through its stroke and the partially compressed and heated air is withdrawn and cooled by some external means to its initial temperature or even lower; then returned to the cylinder to be further compressed, heated and cooled, until the desired pressure is reached. It is evident that such an arrangement would maintain a fairly uniform low temperature in the air volume throughout the stroke, giving very close to isothermal compression.

Such a proceeding is evidently not practical. But the same results may be obtained by compressing in several cylinders, in the first of which moderate pressure and temperature is reached and the air in this condition discharged through a cooling device which restores its initial temperature; then admitted to another cylinder for further compression and heating; again withdrawn and cooled and again compressed. This is a stage of compound compression. An average of the practice of the leading builders permits single stage compression for pressures up to 70 pounds or under some conditions to 100 pounds; two-stage compression for pressures of 75 to 500 lbs.; three or four-stage (preferably in duplex compressors) for pressures of 500 to 1,500 lbs., and four-stage compression for pressures from 1,500 lbs. up.

A three-stage straight line machine should only be used for small or moderate capacities. Above this, the duplex [illegible] would be preferred because of its balanced construction and of the readiness with which it is compounded.

The primary object of compound compression is a saving of the power required by what may be called the heat element in compression. The degree to which this is accomplished depends entirely upon the efficiency of the intercooler. The ideal intercooler would be one which would reduce the temperature of the cooling water. This probably cannot be realized, but a good practical standard demands that the intercooler shall deliver air at a temperature not more than 10 degrees above that of the cooling water.

The successful intercooler involves six fundamental requirements. It must provide for a complete and minute sub-division of the air passing through it, that the heat may be dissipated without any dependence upon the best conducting qualities of the air itself. The air should be split up into thin sheets or streams so as to dissipate its internal heat. There must be an ample cooling surface presented to this subdivided air stream. The circulation of the cooling water must be properly directed in relation to the flow of the air, and its velocity must be such that the maximum amount of heat will be carried away without waste of water. All air passages must have ample cross section, that the velocity of air may be such as to give a length of contact with the cooling surfaces sufficient for the complete removal of the heat. Expansion and contraction must be provided for that there will not be a leakage of air or of water.

Compound air compression has important bearings upon other features of compression economy. It reduces the average structural stresses, resulting in a higher factor of safety and a longer life for the machine with a given weight of metal. The maximum stresses encountered in compression in two stages are only 55 or 60 per cent. of what they are in single stage compression to the same pressure. The reduction of stresses here referred to is felt not only in the machine structure but in the air valves, which show a notably easy operation under compound conditions. Another advantage of compound compression is an improved steam economy if the compressor is steam driven. The averaging of the stresses throughout the stroke, permits the work to be done, with a lower M. E. P. in the steam cylinder, which means a shorter cut-off and a greater steam economy. The reduced terminal stresses permit a higher piston speed with safety, thus improving the steam economy by reducing condensation losses and leakage in the steam cylinder.

High volumetric efficiency results from compound compression, coming from three sources. The first of these is the fact that the clearance pressure in the intake cylinder is lower. The second is a lower maximum temperature in the cylinders so that the entering air is not so much heated. The third is a reduction of leakage consequent upon the reduced extremes of pressure in each cylinder. Compound compression results in more efficient lubrication of the machine because of the lower temperatures involved. This means easier running, improved mechanical efficiency, less wear, lower repair costs, reduced leakage losses, and longer life. Compression in stages results in the delivery of drier air, a feature of great importance where the air is used under conditions which may result in freezing up of the exhaust ports. This also largely obviates the accumulation of water in pipe lines.

Air Valves

The air valves of a compressor are probably the most vital parts of a machine. While the number of different types of air valves is greater than the number of compressor builders, yet they may be broadly classified in two groups. Mechanically actuated valves have a positive motion derived through some mechanical connection from the rotating or reciprocating parts of the compressor. Poppet or automatic valves are operated wholly by differences of pressure. There are other designs of air valves in use today which cannot be exactly placed in either class but these need not be considered at this time as they generally are applied for special purposes and in special cases.

Without going into a detailed discussion of the many different types of air inlet valves, some general observations may be made as to their function and requirements. The function of an inlet valve is to admit the maximum volume of cool, clean air to the cylinder, with the least expenditure of power; to keep this air in; and to continue to perform this duty indefinitely at the least total cost. Analysis of this function reveals the following requirements of the successful inlet valve.

It must admit a volume of air which will entirely fill the cylinder, this air being as nearly as possible at atmospheric pressure. This calls for an instantaneous and complete opening of the valve, so timed that there shall be no escape of the compressed air in the clearance space. This full opening should be held to the end of the stroke, and short, direct and unobstructed passages should be provided through ports and valves.

It must admit clean air, suggesting a design permitting ready connection to an intake passage or conduit leading to a place free from dust and grit. The air admitted must be as cool as possible —a condition partially met by the consideration just mentioned by which cool air as well as clean air should be supplied. But, more than this, the cool air supplied should nowhere be heated in its course into the cylinder, suggesting that valves, ports and passages shall be so placed as to be cooled by the cylinder jacket.

All the air admitted must be kept in the cylinder, calling for instantaneous and complete closing of the valve at the end of the stroke, with a perfect seating and without any leakage. All the processes outlined here must be carried on with the least possible expenditure of power for the overcoming of friction and the manipulation of the valve gear—a requisite demanding nice adjustment, simplicity of mechanism, perfect lubrication and as few wearing surfaces as possible. This exacting performance must be continued indefinitely, twice each revolution and hundreds of times per minute without undue wear or loss of adjustment. This condition is fundamentally one of correct design, high class materials and workmanship and generous lubrication.

(To be continued)

Second Revision of A. S. M. E. Boiler Code

A HEARING is held by the Boiler Code Committee at least once in four years, at which all interested parties may be heard, in order that such revisions may be made as are found to be desirable, as the state of the art advances. The year 1922 becomes the period of the second revision, the first revised edition of the Boiler Code having been issued in 1918. The Boiler Code Committee plans to hold a Public Hearing in connection with the next Annual Meeting of the American Society of Mechanical Engineers, in December, 1922, to which the membership of the Society and everyone interested in the steam-boiler industry will be invited and where they may present their views.

In the course of the Boiler Code Committee's work during the past four years, many suggestions have been received for revisions of the Power Boiler Section of the Code, as a result of the interpretations issued and also of the formulation of the Locomotive Boiler and the Miniature Boiler Codes. In order that due consideration might be accorded to these recommendations, the Committee began in the early part of 1921 to devote an extra day at each of its monthly meetings to the consideration of the proposed revision. As a result of this many of the recommendations have been accepted and revisions of the paragraphs formulated.

In connection with the revision work, the lack of rules and specifications relative to pipe, pipe material and fittings for use in connection with steam boilers up to the flanges for the connection of the first valves, has been apparent. The Committee has endeavored, at the urgent request of many manufacturers, to supply this lack by rules and specifications which have been prepared in co-operation with the American Society for Testing Materials. These rules and specifications are here published and it is the request that they be fully and freely discussed so that it may be possible for anyone to suggest changes before the rules are brought to final form and presented to the Council for approval. Discussions should be mailed to C. W. Obert, Secretary to the Boiler Code Committee, 29 West 39th Street, New York, N. Y., in order that they may be presented to the Boiler Code Committee for consideration.

Rules for Pipe, Pipe Material and Fittings Used on Steam Boilers

X-1. Piping and Fittings.—The piping and fittings used on boilers up to the flanges for the connection of the first valves from the boiler on steam outlets, feed lines and blow-off lines shall conform to the rules given in X-1 to X-6, and it is desirable that all piping, valves and fittings used on steam and exhaust lines including the vacuum system and drain lines; all water lines, including boiler-feed suction and discharge lines; and all boiler blow-off lines shall conform to them.

X-2. Steam Pipe.—Piping for steam mains carrying saturated or superheated steam may be of welded or seamless pipe made of wrought iron or steel. For sizes above 3 in. in diameter the steel pipe shall be of open-hearth steel. All pipes shall be straight and free from blisters, cracks, laminations and other injurious defects. Liquor marks and lap-seam lines incidental to the manufacture of pipe is to be inspected separately for defects on the inside and outside, noting particularly the character of the cross-section when cutting off crop ends. Pipe up to 3 in. in diameter may be butt-welded or lap-welded while that above 3 in. in diameter shall be lap-welded. Pipe material shall correspond with that required by the specifications of wrought-iron and steel pipe included in Par. X-9, et seq.

X-3. Thickness of Steam Pipe.—In determining the thickness to be used for pipes at different pressures and for temperatures not exceeding 700 deg. Fahr., the following formula is to be used:

$$P = \frac{2\,S\,(t - 1/16)}{D}$$

where:

P = the working pressure in lb. per sq. in. above atmosphere
t = thickness of walls in inches
D = inside diameter of pipe in inches
S = 3500 lb per sq. in. for seamless steel pipe
= 3200 lb. per sq. in. for lap-welded steel pipe
= 2500 lb. per sq. in. for butt-welded steel pipe
= 2500 lb. per sq. in. for lap-welded iron pipe
= 2000 lb. per sq. in: for butt-welded iron pipe
= 2000 lb. per sq. in. for brass pipe
= 2000 lb. per sq. in. for copper pipe.

X-4. Feed Lines.—High-pressure hot-water and cold-water lines may be made of welded or seamless pipe of wrought-iron or steel as called for under X-2. Where the water contains corrosive material or air, brass or copper tubing may be used. In determining the thickness of water pipe the following formula will be used:

$$P = \frac{2\,S\,(t - 3/32)}{D}$$

where: P = water pressure in lb. per sq. in.
t = thickness of pipe in inches
D = inside diameter of pipe in inches
S = 2625 lb. per sq. in. for seamless steel pipe
= 2400 lb. per sq. in. for lap-welded steel pipe
= 1875 lb. per sq. in. for butt-welded steel pipe
= 1875 lb. per sq. in. for lap-welded iron pipe
= 1500 lb. per sq. in. for butt-welded iron pipe
= 1500 lb. per sq. in. for brass pipe
= 1500 lb. per sq. in. for copper pipe.

Where brass pipe is desired for finish or for any other reason it may be used. The brass and copper pipes used shall correspond to the specifications given under Pars. ..... and the brass pipe shall be half-annealed in order to leave it in proper condition for use in feed-water piping.

X-5. Blow-off Piping.—Blow-off pipe is to be of extra strong size and to be made of genuine wrought iron or steel as preferred.

X-6. Pipe Bends.—Pipes when bent may be made of steel or wrought iron and after bending are to be free from buckles and blisters and practically circular in cross-section. They are to be bent before being threaded or flanged, and where flanged they are to be refaced to dimensions so that they may be bolted or faced without forcing. Where possible, the tangent length of pipe at the end of each bend should be of a length equal to at least twice the nominal diameter of the pipe, although tangents may be used with lengths which are equal to the nominal diameter of the pipe. The advisable radius to which pipe should be bent should be five or six times the nominal diameter of the pipe, although pipe may be bent to a radius equal to four times the diameter of standard pipe and three and one-half times the diameter for extra strong pipe up to 12 in. The thickness of the pipe is to be determined by the formula given in X-3. The boiler-feed line bends are to conform with the above, while for blow-off lines the rules are to be applied to extra strong pipe.

Specifications for Welded and Seamless Steel Pipe

X-7. These specifications cover "standard" and "extra strong" welded and seamless steel pipe, but not "double extra strong" pipe. Pipe ordered under these specifications are intended for bending, flanging and other special purposes.

I—Manufacture

X-8. (a) The steel for welded pipe shall be of soft weldable quality made by the Bessemer or open-hearth process. The steel for seamless pipe shall be made by the open-hearth process.

(b) Welded pipe 3 in. or under in nominal diameter may be butt-welded, unless otherwise specified. Welded pipe over 3 in. in nominal diameter shall be lap-welded.

II—Chemical Properties and Tests

X-9. Open-hearth steel shall conform to the following requirement as to chemical composition:

Phosphorus, not over 0.05 per cent.

III—Physical Properties and Tests

X-10. (a) The material shall conform to the following minimum requirements as to tensile properties:

	Welded Bessemer	Welded Open-Hearth	Seamless Open-Hearth
Tensile strength, lb. per sq. in.	50000	45000	48000
Yield point, lb. per sq. in.	30000	25000	26500
Elongation in 8 in., per cent.	18	20	18

(b) The yield point shall be determined by the drop of the beam of the testing machine.

X-11. (a) Welded pipe shall be tested at the mill to the hydrostatic pressures specified in Table 1.

TABLE I. HYDROSTATIC PRESSURES FOR WELDED STEEL PIPE

Black and galvanized. Pressures expressed in pounds per square inch).

				"Standard" Pipe		"Extra Strong" Pipe	
Nominal Inside Diameter, In.	Actual Inside Diameter, In.	Actual Outside Diameter, In.	Weight of Pipe per Foot, Plain Ends, Lb.	Butt-weld	Lap-weld	Butt-weld	Lap-weld

For pipes over 12 in. in inside diameter, the test pressures should be calculated by the formula P=2St D, in which P= pressure in pounds per square inch; S=fiber stress=12,000 lb. per sq. in.; t=thickness of wall in inches; D=diameter in inches.

(b) Seamless pipe shall be tested at the mill to hydrostatic pressures not exceeding that required by the formula:

$$P = \frac{2\,S\,t}{D}$$

in which P=pressure in pounds per square inch; S=allowable fibre stress =16,000 lb. per sq. in.; t=thickness of wall in inches; and D=inside diameter in inches.

X-12. (a) For lap-welded pipe over 2 in. in diameter, a section of pipe 6 in. long shall be flattened between parallel plates until the distance between the plates is one-third the outside diameter of the pipe with the weld located 45 deg. from the line of direction of the applied force, without developing cracks.

(b) For butt-welded pipe over 2 in. in diameter, a section of pipe 6 in. long shall be flattened between parallel plates until the distance between the plates is 60 per cent. of the outside diameter of the pipe with the weld located 45 deg. from the line of direction of the applied force, without developing cracks.

X-13. For pipe 2 in. or under in diameter, a sufficient length of pipe shall withstand being bent cold through 90 deg., around a cylindrical mandrel the diameter of which is 12 times the nominal diameter of the pipe, without developing cracks at any portion and without opening the weld.

X-14. (a) Test specimens shall consist of sections cut from a pipe. They shall be smooth on the ends and free from burrs.

(b) Tension test specimens shall be longitudinal.

(c) All specimens shall be tested cold.

X-15. One of each of the tests specified in Pars. X-10, X-12 and X-13 may be made on a length in each lot of 500 or less, of each size. Each length shall be subjected to the hydrostatic test.

X-16. If the results of the physical tests of any lot do not conform to the requirements specified in Pars. X-10, X-12 and X-13, retests of two additional pipes shall be made, each of which shall conform to the requirements specified.

IV—Workmanship and Finish

X-17. For pipe 1½ in. or under in inside diameter, the outside diameter at any point shall not vary more than 1/64 in. over nor more than 1/32 in. under the standard size. For pipe 2 in. or over in inside diameter, the outside diameter shall not vary more than 1 per cent. over or under the standard size.

X-18. Unless otherwise specified, pipe shall conform to the following regular practice:

(a) Each end of standard welded pipe shall be threaded.

(b) Extra strong welded pipe and standard and extra strong seamless pipe shall be furnished with plain ends.

(c) All threads shall be in accordance with the American Standard and cut so as to make a tight joint when the pipe is tested at the mill to the specified internal hydrostatic pressure. The variation from the standard, when tested with the standard working gage, shall not exceed a maximum of one and one-half turns either way.

(d) Each length of threaded pipe shall be provided with one coupling, having clean-cut threads of such a pitch diameter as to make a tight joint. Couplings may be made of wrought iron or steel.

X-19. The finished pipe shall be reasonably straight and free from injurious defects. All burrs at the ends of the pipe shall be removed.

V—Inspection and Rejection

X-20. The inspector representing the purchaser shall have free entry, at all times while work on the contract of the purchaser is being performed, to all parts of the manufacturer's works which concern the manufacture of the pipe ordered. The manufacturer shall afford the inspector, free of charge, all reasonable facilities to satisfy him that the pipe are being furnished in accordance with these specifications. All tests and inspection shall be made at the place of manufacture prior to shipment, unless otherwise specified, and shall be so conducted as not to interfere unnecessarily with the operation of the work.

Each length of pipe which develops injurious defects in shop working or application will be rejected, and the manufacturer shall be notified.

Specifications for Welded and Seamless Wrought-Iron Pipe

X-21. These specifications cover "standard" and "extra strong" welded wrought-iron pipe, but not "double extra strong" pipe.

X-22. All pipes to be used on locomotives and cars shall be of coiling or bending quality.

I—Manufacture

X-23. (a) The iron shall be made from muck bars, made from puddled pig iron, free from any admixture of iron scrap or steel.

(b) All pipe 3 in. or under in nominal diameter may be butt-welded, unless otherwise specified. All pipe over 3 in. nominal diameter shall be lap-welded.

X-24. Iron Scrap. This term applies only to foreign or bought scrap and does not include local mill products, free from foreign or bought scrap.

II—Physical Properties and Test

X-25. (a) The material shall conform to the following minimum requirements as to tensile propertites:

Tensile strength, lb. per sq. in.	40,000
Yield point, lb. per sq. in.	24,000
Elongation, in 8 in., per cent.	12

(b) The yield point shall be determined by the drop of the beam of the testing machine. The speed of the cross-head of the machine shall not exceed ¾ in. per minute.

X-26. All pipe shall be tested at the mill to the hydrostatic pressures specified in Table I.

X-27. A section of pipe 6 in. in length shall be flattened until broken by repeated light blows of a hammer or by pressure; the fracture developed shall have a fibrous appearance.

X-28. For pipe 2 in. or under in diameter, a sufficient length of cooling or bending pipe shall withstand being bent cold through 90 deg., around a cylindrical mandrel the diameter of which is 15 times the nominal diameter of the pipe, without developing cracks at any portion and without opening the weld.

X-29. (a) Test specimens shall consist of sections cut from a pipe. They shall be smooth on the ends and free from burrs.

(b) Tension-test specimens shall be longitudinal.

(c) All specimens shall be tested cold.

X-30. One of each of the tests speci-

Oil Fuel Enthusiasm

WE NOTE in practically every daily paper we pick up, and in our passage through the streets, that there are a number of individuals or corporations offering the public oil burning apparatus for domestic purposes. This sudden rush into the field of oil fuel appliances is of course an effect of the feared shortage of coal, and was to be expected.

There is no reason why oil should not be capable of being burned successfully in a domestic furnace any more than in a steam boiler, but the question in both cases, is which is the most advantageous? With oil, of course, there is no removing of ashes, and no cleaning of grates, at least there should not be. So far that is a distinct advantage to the householder, and there are no doubt many such who would be prepared to pay for that convenience, in any case. As regards economy of operation, that depends on a large number of factors, such as the type of burner, the furnace arrangements, and the relative cost of oil and coal. It must not be imagined that oil is inevitably cheaper than coal to burn. It can be burnt just as wastefully, though the waste is perhaps not so apparent to the eye. From the point of view of cost, when the price of oil per pound is in the neighborhood of double the cost of coal, then the economical advantage vanishes.

Some of these burners are being offered to the public at a price which can only be characterized as excessive. Some of them have merit from an engineering point of view, others are perhaps best described as crude. We are of the opinion that a really adequate oil burner, that could be handled by the female portion of the family, and that was so constructed as to give the most efficient combustion results with low priced oil, would be a distinct benefit to the community. We do not mean that it would displace coal, but it would certainly act as a regulator on the price demanded for coal, while the coal would also act as a deterrent on undue inflation of the price of oil. We have seen a number of oil burners developed by earnest and enthusiastic gentlemen, and we have been shown beautiful colored flames, etc., but we have not yet seen such a thing as authentic figures on the performance of any of them.

We would advise the general public to examine very carefully, and if possible with the aid of someone thoroughly familiar with the subject, any oil burning apparatus they may feel inclined to purchase. It is hard to escape the impression that some of those offered have been developed purely with the idea of cleaning up while the present coal shortage is making people anxious to buy anything that promises relief.

A Personal Message

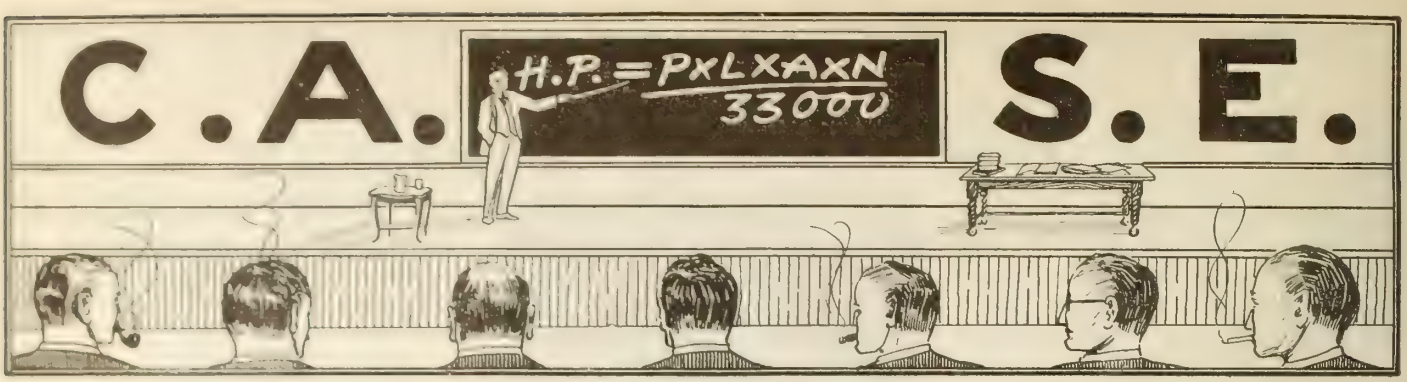
IN THE issue of May 5th, 1920, of this journal, the writer addressed a message under this heading to the readers of "Power House." That was on the occasion of his taking over the editorial chair, and now, on this occasion, the same medium is being used to wish the readers farewell. During the intervening time, it has been a privilege to gain a closer acquaintanceship with the subscribers and contributors of "Power House," and in some small measure to have assisted them from time to time with the problems of their daily work. It is with a feeling of regret that is unavoidable, that these pleasant relations are concluded. However it is a source of pleasure to the writer that the new sphere of activities to which he is called will allow him to gain perhaps a closer personal touch with at least some of his old friends, his future duties being that of Manager and Chief Engineer of the Boiler Insurance Department of the General Accident Assurance Co.

As has so often been said in these columns, the usefulness of a magazine of this kind depends to a large extent on the sympathetic support of the readers, and an earnest appeal is extended to them for their support in the future, as it has been so loyally given during the present editor's incumbency. The paper can be made largely a medium for the betterment of the status of the engineer in general, by the use of its columns freely in the discussion of their problems and difficulties, not only in a technical, but in a personal way.

The "Power House" as the only Canadian magazine published for Canadian engineers, dealing with conditions as they prevail in Canada, as well as the progress of all branches of power plant engineering as they develop in different parts of the world, is worthy of the support of all those whose lives are bound up with Canadian development along these lines.

It is the earnest wish of the writer that he may be privileged to see the power plant engineer in Canada make a steady progression, until he attains the standing in the industrial community to which his qualities and faithful application to duty entitle him, and in whatever small way he can help this development, his services will willingly be given. In education lies their chief hope, and all their endeavors should be directed towards the attainment of the highest possible standard along that line.

To the readers, contributors and advertisers of "Power House" the writer wishes "Good-bye and good luck."



Going Into the Burning Oil Question

After Hearing a Number of Arguments Pro and Con at a C.A.S.E. Meeting, "Johnny Shovel" Goes Out and Does Some Investigating for Himself

By "JOHNNY SHOVEL"

A FEW days after the C.A.S.E. meeting, we got thinking about the talk and the discussion on oil fuel, particularly about the argument as to when conditions make it cheaper to burn oil than coal.

The discussion brought up several points on which the wise ones could not give the data. For instance, not a soul in the hall knew whether we Canadians buy oil by the U.S. gallon or the British Imperial gallon. Naturally, it makes a big difference, for the gallon of oil U.S. measure weighs almost 2 lbs. less, and does nearly one H.P. less work than the Imperial gallon will do.

For figures we got some pretty arguments. It being one of the rules laid down by the Educational Committee that no text boks can be used in the hall on meeting nights. One man's memory is considered as good as another's, so the point cannot be settled by recognized authority. What we were told about the various fuels lost a good deal of its value, because, in most cases, neither the speakers themselves nor we who heard them, knew the exact wording of the law applied or the correct formula.

Working Without Tools

Getting a man to do one of those questions without a handbook is like sending a workman to take measurements without a rule, and if we were picked on to do one, we know we couldn't "think on our feet" and we certainly would ask the boss for the keys to the tool cupboard, meaning the library, for the Constitution of the C. A. S. E. provides for a library and question time is certainly the time to us it.

The Reference Library

The question was "How do you figure the total cost of the two fuels to find out which one is the cheapest to burn?"

The man who had been talking on oil told us there were a great many things to think of besides the actual cost of the fuels themselves. Any one considering oil should make sure that his plans for tanks, piping, etc., are accepted by the local authorities and his insurance company. Most important of all is to know what the nearest branch of the oil company will supply the oil for and how long the price will remain fixed. After that one can begin to consider things directly concerned with the production of power, such as the water each fuel will evaporate, the efficiency of the boilers, the cost of labor for firing and handling fuel and waste.

He said he knew of a chart in some handbook which compares oil and coal for price, with boiler efficiency considered, and if he remembered it correctly, the chart showed that when oil was 7c per gallon, coal would be $8.00 a ton. He was a witness for oil.

Another man declared that they had worked it out for his plant and it was cheaper to burn coal at $15.00 per ton. He was a coal man.

Back came the man who wrote about the oil, to put the figures for his plant on the blackboard. He said he often got better than 15 lbs. of water evaporated per lb. of oil, but he would say 14 lbs.

Water evaporated per day (24 hrs.) 480,000 lbs.

Oil required 480,000÷14=34,300 lbs.

Weight of 1 gal. oil is approximately 10 lbs.

Therefore 34,300÷10=3,430 gals. are required.

3,430 gals. at 7c per gal.=$240.10 per day for oil.

He would allow that 8 lbs. of water could be evaporated per lb. of coal, therefore 480,000

---

8 x 2,000 (lbs. per ton)=30 tons of coal

$240.00÷30=$8.00 per ton for coal.

A pump was needed to put the oil in the service tank at the top of the boiler room, which was 25 ft. of a lift

34,300 lbs. x 25 ft.

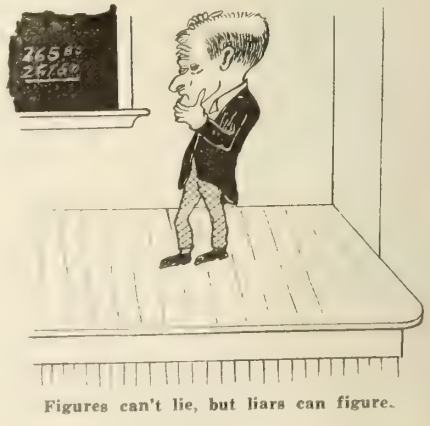
33,000 = 26 h.p. for pumping

allowing that each h.p. required 2.3 lbs. of oil

26 x 23=or say, 60 gals. to run the pump

60 gals. at 7c=$4.20 for pumping.

For steam atomizers it would take from 2 to 5% of the steam made by the boiler to break up the oil in the burners. He thought 4% was fair enough. Allowing 34.5 lbs. water for h. p. then



Figures can't lie, but liars can figure.

480,000=13,913 h.p. was developed.
———=13,913 h.p. was developed.
34.5
4% of 13,915=557 h. p. x 23 lbs. oil per h. p.
=1,280 lbs.=128 gals.
128 gals. at 7c=$9.00 for atomizing.

His labor for 3 shifts was	$ 12.00
Oil	240.00
Pumping	4.20
Atomizing	9.00
	$265.30

When he operated the same plant on coal the

Labor was	$ 21.50
30 tons of coal at $8.00	240.00
	$261.50

Evidently, he expected to show that he was making a saving with oil, for he stood scratching his head and staring at the result as though he did not understand it. If he had claimed an evaporation of 15 lbs. per lb. of oil, he would have made it come out the way he wanted it

480,000÷15=32,000 lbs.=3,200 gals. at 7c=$224.00

but he got excited and could not see that he had been too generous about the evaporation and several other things.

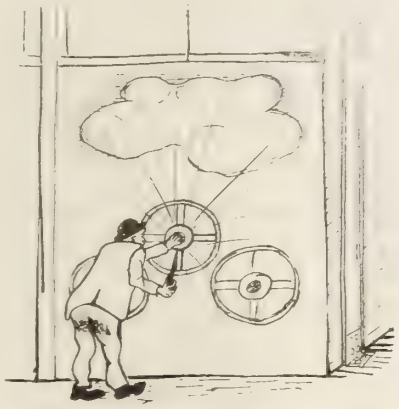
To us he made very plain the advantage of having equipment which would give that extra lb. of water evaporated per pound of oil. We would like to have the saving for a year for our salary, and we would not look for a bonus at Christmas either.

Another man who said that he burned oil in his heating plant and that he was evaporating about 150,000 lbs. of water every 24 hrs., made the statement that he had been able to show a saving with oil and he would be glad for anyone to see his records. He could show what he had paid for oil month by month and the price of coal on the same date. His records covered 3 years and he frankly admitted that the first year it would have been better and cheaper to have burned coal.

To burn the oil efficiently it was necessary to have proper equipment and first class men. After the first year, he got his furnaces right and the men trained and he got results that paid him to fire oil. We gathered from his talk that an inexperienced fireman can waste oil even more easily than a coal shoveller can waste coal. That tanks and piping had to be of the best material and well attended to because the oil would get through where water would not go. Some of the troubles he got during his first year were due to the quality of the oil unloaded on to him, and he advised us to be careful of the stuff and see that it does not contain more water and sulphur than our specification calls for.

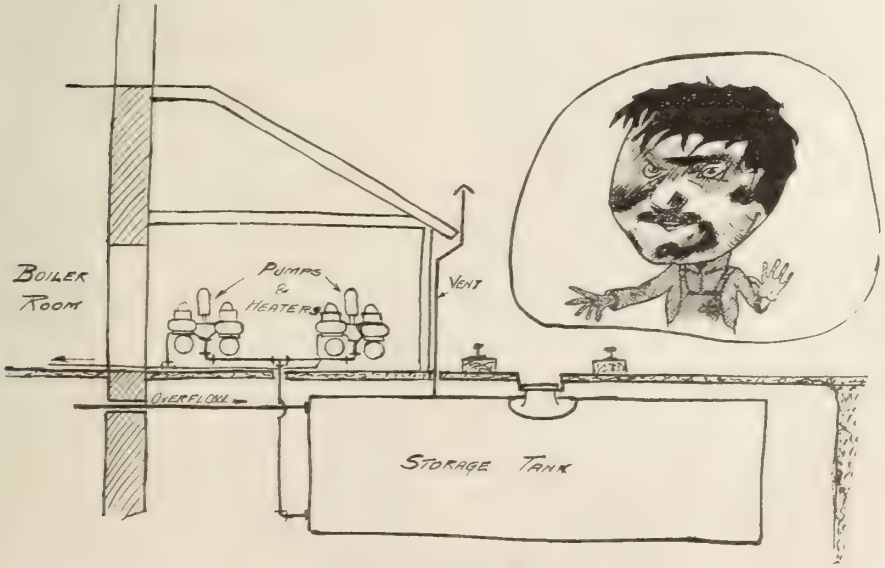
Some oil is wasteful because of the quantity of material in it which settles to the bottom of the tank. This "sludge" is practically a dead loss. It has to be thrown away because it will stop up all the burners.

Next day we went to a tech. library and hunted up all the evidence in the case of Coal vs. Oil. We found several books giving comparisons according to



Lighting Up

the writer's experience, but no two of them agreed to a dollar. One gave almost the same figures that we had on the blackboard, stating that oil at 7c was equivalent to 13,000 B. T. U. coal at $8.16 per ton (2,000 lbs.)



No Dirt With Oil Fuel.

Oil! (Leak).

One chart, by a well known firm of combustion engineers, showed that 7c oil equalled coal at $9.00, and in view of their experience we were inclined to think that their dope would be about right to follow. That is, if coal cost more than $9.00 a ton, it would be cheaper to burn oil at seven cents per gal. Imp. measure.

But we didn't leave it at that. Next day we rose up early in the morning, and still being a free citizen though on holidays, we decided to look into all the plants that we could find where oil was being used for fuel.

Oil fired plants are not so plentiful as you might think and we did not find as many as we expected. Some of the places which we were directed to had changed back to coal shortly after the war. Nevertheless, in the course of a strenuous day, we saw nine plants using oil. Six of them were strictly heating plants, only 3 of which were lighted up at the time we called, and these were running very light till frost.

Public Hospital Arrangement

The first was a public hospital and the arrangement for atomizing was operated by a motor. We didn't like it, because the power might go off and leave them without heat. The engineer claimed an evaporation of 17 lbs. of water to a lb. of oil, but he had no means for checking it, so we took his estimate with a grain of salt. He complained that the quantity of oil that the equipment would handle was limited, and he couldn't get his safety valve to blow, no matter how he pumped. We couldn't make out what the trouble was, but as there looked to be a pretty good chance that the safety valve was stuck, we made a hurried departure.

The next plant was in a hotel. Under a boiler of about 75 h.p. we found a burner of the engineer's own invention. He was rather chary of giving information about it but bragged mightily of the saving he was making for the company. We didn't want to steal his ideas, but we couldn't help but notice that the oil pump was operating around 150 lbs. pressure. The fire was dazzling white, and that made our chance to see the burner very poor, so we're not sure if there was any more to it than just an elbow, plugged and a slot sawed in it.

The inventor told us he was burning only about 200 gals. of oil per day, but the oil tank happened to be putting some in when we came up onto his street and the driver said he filled up the 500 gal. tank every other day.

That same driver directed us to go to another hotel "if we wanted to see how oil should be burned." There we found the writer of the paper on oil, who was covering reams of paper in an effort to design his methods of keeping his records for the next year. When we say he was operating all the machines necessary for "the house" we have told his story outside the boiler room. We won't try to describe the roar of those steam burners, nor the long smooth rush of the flame. It was awe inspiring but it raised a question "how about tubes." Did he replace very many? He admitted that he did put in quite a few, but he blamed it to the fact that the oil was very high in sulphur.

It seems that the sulphur in oil doesn't attack the tanks or piping like the same element in coal would attack the burners and chutes. But if the burner is set so that the flame is driven on to the tubes, then look out for trouble. His burners were pointed so the ordinary flame did not reach the tubes, but he had an idea that as the slots in the tip wore, the cone increased in size and then the drops had mass enough to affect the distance and the direction they would travel. He had to watch the tips of the burners so the cone wouldn't get too large on him. We wondered if it would be possible for the oil to come through in occasional slugs which would weigh enough to make them travel to the tubes and cause damage by burning them. We certainly admired that fire, but could easily imagine a bit of scale in the tubes would start, with a heat like that close up on the outside.

We followed the oil from the storage tank to the burners and while we found quite a few things contrary to what our reading on oil fuel had led us to expect, there were lots of nifty ideas, particularly in piping. For instance, the oil could be bye-passed so there was small chance that the supply would fail at the burners. There were steam lines for heating and for fire protection.

There was a heater around the suction pipe inside the big tank. Guess they would have had a hard time in winter to pump without that, for oil doesn't handle easily below 80° F.

Even at that temperature, it is sticky stuff and hard to pump, which perhaps explains the high cost of pumping as put on the board at the C. A. S. E. meeting.

While we were making a diagram of the tanks, pumps and piping, we discovered the man who looks after them and made a sketch of him too. And then they tell you oil is "so clean to burn."

Another Example

We stuck around that plant till we thought we had worn our welcome out,

for they started telling us of a larger one. Then of course, common decency sent us away, but really we should have gone back and thanked them, for their recommend was hardly expansive enough for the plant they sent us to.

This time the boilers were big and running at 150% rating and better. The burners atomized the oil mechanically and we were particularly requested to note the flame, that it was soft and bluish and without any definite outline to it, so there was very little chance for impingment on the tubes or damage to them.

"It's the only burner for a plant like this," declared our new friend the Chief. "Those mechanical atomizers you have seen will break up light oil well enough, but here we can't afford to pay 10c a gal. for oil. We don't pay half that, so the muck we get has to be divided into particles about one tenth the size which those little burners make it, to get the necessary surface exposed to vaporize it at the rate we want it to burn.

"We make it warm so we can pump it, and hot so it atomizes easily. All the oil passes through the heater after it leaves the pump and is about 250° F. at the burner, more or less, depending on the oil we are using.

"Our load has its ups and downs, but there is no difficulty because these burners are very flexible and we can control the quantity of oil to suit the requirements, also the air for combustion. The quantity of air is just as important as the right amount of oil, but the wicket at the burner working with the damper gives us so close a control that our CO_2 readings are always good." There was very little waste at that plant and we were not surprised at or doubtful of the claim for 80% efficiency.

The chief showed us and told us many things about oil including a story about a new man in the stores department who hailed from Texas. Of course the new man didn't know they used oil for fuel so it was a wonderful discovery to find a patch of oil on the ground, though the same oil had come from a leaky pipe.

When we opened a discussion on the price of oil as compared with that of coal, we found our new friend's weak spot. He didn't keep any record of comparative coal price. They had a long contract, so what was the use?

After we got back to our own stamping ground, we thought it all over and came to the conclusion that in times like these, when the country is full of strikes the fellow that didn't have the strike would have the cheapest fuel. In normal times the price of oil would probably be adjusted to the price of coal so nearly that it was fifty-fifty which fuel a man burned if he had equal experience with both. But if he knew one and not the other, then let him burn the one he knows best with all the care he can and he will get the desired results.

WASTE HEAT RECOVERED

Tests made at a large water-gas plant in Illinois by W. A. Dunkley, gas engineer, of the United States Bureau of Mines, using coal for No. 2 Illinois seam as generator fuel and operating with waste heat boilers, showed that approximately 12 per cent of the heat introduced as fuel was recovered by the boilers, the steam generated corresponding to about 600 boiler horse power, more than enough to operate the gas sets. Without the waste heat boilers, this energy would have been totally wasted. Recoverable heat was still going to waste.

SECOND REVISION OF A. S. M. E. BOILER CODE

(Continued from page 28)

fied in Pars. X-25, X-27 and X-28 may be made on a length in each lot of 500 or less, of each size. Each length shall be subjected to the hydrostatic test.

X-31. If the results of the physical tests of any lot do not conform to the requirements specified in Sections X-25, X-27 and X-28, retests of two additional pipes shall be made, each of which shall conform to the requirements specified.

III—Workmanship and Finish

X-32. (a) For pipe 1½ in. or under in inside diameter, the outside diameter at any point shall vary not more than 1/64 in. over nor more than 1/32 in. under the standard size. For pipe 2 in. or over in inside diameter, the outside diameter shall vary not more than 1 per cent. over or under the standard size.

X-33. Unless otherwise specified, pipe shall conform to the following regular practices:

(a) Each end of standard pipe shall be threaded.

(b) Extra strong pipe shall be furnished with plain ends.

(c) All threads shall be in accordance with the American Standard and cut so as to make a tight joint when the pipe is tested at the mill to the specified internal hydrostatic pressure. The variation from the standard, when tested with the standard working gage, shall not exceed a maximum of one and one-half turns either way.

(d) Each length of threaded pipe shall be provided with one coupling, having a clean-cut thread of such a pitch diameter as to make a tight joint. Couplings shall be of wrought iron.

X-34. The finished pipe shall be reasonably straight and free from injurious defects. All burrs at the ends of the pipe shall be removed.

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

HEATING SURFACE OF SCOTCH BOILER

Question:—Please explain in your next issue of the Power House how to figure the heating surfaces of a Scotch marine boiler?

Answer:—The heating surfaces of a Scotch marine boiler are the furnaces, from the level of the fire bars, the plates of the combustion chamber, and the crown of the combustion chamber, also the tubes. This will be practically half the diameter of the furnace, x length in feet, x number of furnaces. Add to this the area of the side and back plates of the combustion chambers, and the area of the crowns. The combustion chamber tube plate is a heating surface, but from its area must be deducted the cross sectional area of the tubes. The area of the tubes will be the outside diameter of the tubes, x 3.1416 and divided by 12, the result being multiplied by the number of tubes and the length in feet. In figuring the combustion chamber area, if strict accuracy were aimed at, the area of the stays would have to be deducted, but the error including the stays is a small one. We could say in formula form for the heating surface

$$\tfrac{1}{2}D \times 3.1416 \times L \times N + (\text{area of c. c. shuts} + \text{area of crowns} - \text{total area of tubes}) + \frac{d\ \pi}{12} \times l \times n$$

Where D = dia. of furnaces, L = Length of furnaces, N = Number of furnaces, d = diameter of tubes, l = length of tubes, n = number of tubes.

Area of tubes to be subtracted is, of course, cross-sectional area, or $d^2 \times .7854$. The combustion chambers may not be all the same size. The bottom of the combustion chambers below the bridge wall might be considered a heating surface, but as this space speedily fills up with soot, as a rule it may be neglected.

CIRCULATION OF WATER

Question:—In a recent argument between a locomotive engineer and myself re the circulation of water in bottom legs of a locomotive boiler, he argued that the water at the bottom of a boiler was not hot during any time that the steam in the boiler was at or above 212 degrees, and to prove his argument, placed an ordinary tea-kettle full of boiling water on his hand which he claimed was not hot till the steam fell below 212 degrees. I claim that owing to the water being expanded to a large degree at this temperature, and the bottom of the kettle being hot, the water barely touches the bottom before it turns to vapor; this vapor rises to the top until the temperature falls below 212 degrees, and then the water lies stationary on the bottom of the boiler or tea-kettle, when the dead heat of the water is transferred to the plates.

Answer:—Circulation in a boiler, or tea-kettle if you will, occurs from the bottom, or the portion in contact with the flame, towards the top, in a vessel such as a tea-kettle the circulation being in fairly straight lines. In the tea-kettle the water being at atmospheric pressure, boils at 212 degrees and in raising steam on a boiler the initial raising of steam takes place at atmospheric pressure. As the pressure increases the temperature of the steam and the water both increase. If the containing vessel is of such construction that ample circulation spaces are provided, the temperature all over the boiler will be approximately the same, but in a vessel such as a locomotive boiler, with its restricted water legs, circulation is not so free. It is thus possible that water may remain in the water legs and fall below the temperature due to its pressure, and if the circulation is very poor, with the bottom of the water leg below the fire grates, the temperature may fall below the boiling point. The same thing occurs in the marine type of boiler, if special care is not taken to ensure thorough circulation while steam is being raised. In the horizontal type of boiler, which may be compared to the tea-kettle, inasmuch as the flame is directly beneath the boiler plate, there is no possibility of the water falling below the temperature of the steam, but on the other hand it may be slightly higher. It is a source of considerable surprise to us that your friend was able to place a kettle full of boiling water on his hand, unless he had taken special precautions to avoid burning beforehand. If as you surmised, there was no water in contact with the bottom of the kettle, then the kettle would burn, as steam is a very poor conductor of heat. It is owing to the fact that the water by rapidly circulating carries away the heat that is passing through the thin plate and distributes it to the rest of the water that burning of the plate is avoided. As the hot water rises from the bottom of the kettle or boiler it does so in the form of a small bubble, enclosing a small amount of vapor, this bubble increasing in size as it reaches the surface, where the pressure becomes less. When the surface is finally reached the bubble bursts, and its vapor content goes to join the steam in the steam space. If you were to leave a kettle long enough exposed to the flame the water would eventually be all evaporated in this way, and there would be nothing to carry away the heat from the metal except radiation, which could not carry it away rapidly enough to prevent the metal becoming red hot, and if sufficient heat available, melting.

You may or you may not be aware of the fact that water can be boiled in a paper bag over a gas jet, providing the flame is not so severe as to pass heat through the paper faster than the water can carry it. Water is not a good conductor of heat, but is a very good carrier, and the circulation of water distributes heat by conveying it. If you fill a bath with cold water, and then turn the hot water tap on you will notice that unless you take means to mix the water up by stirring with your hand, there will be a distinct zone of hot and cold water. In the case of the water leg of a locomotive boiler, the greatest heat is above the fire, which heat is carried by the water in the upper part of the leg by convection up towards the crown sheet and from there towards the barrel of the boiler. In this way it is quite possible for the bottom of the water leg to contain water that has little or no circulation, and this would account for the difference in temperature at this point.

SIZE OF PISTON RINGS

Question:—How are the proper sizes of piston rings arrived at; in what proportion are they made larger than the diameter of the piston or cylinder bore, say, for 3, 4, or 6 inch cylinders? Also how is the efficiency of the ligaments between the tubes of a boiler arrived at so that part of a boiler will be equal in strength to the rest of the boiler?

Answer:—A fairly good rule to use is that the diameter of the ring before cutting should be equal to the diameter of the cylinder plus diameter x .03. Thus with a 4-inch cylinder the ring before cutting would be $4 + 4 \times .03 = 4.12$, which is practically 4⅛. The circumference of the ring will be then longer than the circumference of the cylinder by $.125 \times 3.1416 = .3927$, and this will

be the amount to be cut out approximately. When turning the ring it should be turned with the inside diameter slightly eccentric to the outside, which allows the ring more ease in springing in, than when it is parallel. Using the same rule for a 6-in. piston we would have $6 + 6 \times .03 = 6.18$ dia., which is practically 6-3/16 dia., and a 3 in. ring would be $3 + 3 \times .03 = 3.09$ or 3-3/32 dia. before cutting.

Boiler Tube Ligaments

The strength of the ligaments between the tubes of boilers, when the tubes are in a line parallel to the axis, such as in some types of water-tube boilers, is found by the formula $\frac{P - D}{P}$ = efficiency where P is the pitch and D the diameter of the tubes. The size of the ligament between tubes in a horizontal boiler head must be .3 of a square inch in sectional area, or ¾ in. linear measurement, whichever gives the greatest pitch.

WHAT'S THE ODDS

Just to show how some of the towns in the United States are indifferent to a mere shut-down of a power plant, I was in a city not long ago whose population is about 4000. They have an electric light plant municipally owned, but at 11 o'clock p.m. they shut down, that is, provided they didn't shut down before 11 p.m. In the meantime, to dispel darkness the denizens of the city have to content themselves with matches, candles, kerosene or moonlight.

While I was in that town in a hotel, I noticed that my light was gradually growing dimmer and finally it died down altogether at nine o'clock. Much disturbed I lighted a kerosene lamp which had been provided. I noticed that everybody else was unconcernedly providing light of some kind without cursing or loud talk of any kind. I was the only one who seemed inclined to worry about the situation.

I inquired as to what might be the matter, but no one would venture an opinion on the subject. "It ain't nothin' unusual," I was told.

Disliking the idea of reading by kerosene lamp. I strolled over to the power house to get my information first hand. There I found the fireman just closing up, locking the door. "What's the matter?" I asked. "Nothin'." he drawled. "Why did you shut down so early?" "Ran out of coal." "Why didn't you borrow some?" "'Twa'nt necessary. We're expectin' a car some time tomorrow."

ANNOUNCEMENT

The Beldam Asbestos Packing & General Manufacturing Co., Toronto, have completed arrangements with the Crane Packing Co., of Chicago, for the manufacturing of their products in Toronto. They also handle the selling for the Crane Company in conjunction with their own business.

Should Piston Rods Be Ground?

WHEN the question of the installation of new equipment comes before the management of manufacturing plants to-day, the modern executive requires to be shown the advantages that will be derived by the proposed change of practice before deciding on the best machine for the purpose. Owing to the many factors to be considered it is frequently desirable to exercise a reasonable degree of caution before committing one's self on the adoption of any particular style of equipment.

While there is still some difference of opinion regarding the most efficient method of truing both new and used piston rods, extended tests seem to favor the grinding process. As an instance of the study that has been given to this phase of railway practice the following extract of an article in the Railway Mechanical Engineer may be of interest:

"Notwithstanding the almost universal approval of piston rod grinding, the innate caution of railroad men regarding new devices was strongly illustrated in a large railroad shop recently where it was proposed to install a machine to grind piston rods instead of continuing the older method of turning and rolling them. Those who hesitated to install the new machine said that it must first demonstrate its superiority in a comparative test. Accordingly, a new piston rod was turned and rolled as accurately as possible. This rod was then carefully mounted in a piston rod grinder and ground, with the abrasive wheel just lightly touching the rod. The grinding operation was then stopped and observers noted that more metal was removed at certain places on the piston rod than at others and in some places the abrasive wheel did not touch the rod at all.

"Micrometer calipers checked the accuracy of grinding both as regards taper and roundness of the rod. The fact that more metal was removed by grinding at certain places than at others proved conclusively that the rod, as rolled previous to grinding, was not a true cylinder. This was evidently due to the fact that the rod was non-homogeneous, being softer in some spots than in others, with the result that the roll depressed these soft spots unduly. The grinding machine, on the other hand, exerted hardly any pressure on the rod and removed as much metal from the soft spots as the hard, producing a true cylindrical surface.

"In the days of wick packing the accuracy of piston rods did not make so much difference, but now that metallic packing is used almost universally it is evident that this packing cannot hold steam and last for any considerable length of time unless piston rods are accurately round, smooth and, practically speaking, without taper. That these qualifications are best obtained by the use of modern piston rod grinding machines is evident from the many ground piston rods now in daily use and giving satisfactory service."

USE OF STEAM IN COAL GAS RETORTS

The tendency toward lower standards of quality of gas in public utilities has increased the interest of the gas industry in processes that promise to increase the yield of gas per pound of coal coked, even though attended by a decrease in quality. The introduction of steam during or at the close of the coking process has shown considerable advantage in certain types of gas-making installations, notably in vertical retorts. The Bureau of Mines, through W. A. Dunkley, gas engineer, has co-operated with the American Gas Association in studying the effects of using steam in horizontal retorts, which are commonly used. It was found that the method of admitting steam had much to do with the results obtained. Little, if any, water gas was generated by decomposition of steam in the retort charge, unless the contact between the steam and the charge was intimate. Steam as usually practised in the small gas plant, where the process had been tried, has no advantage. With prevailing standards of gas quality, little advantage can be taken of the use of steam, even if properly applied, as the production of any appreciable volume of water gas considerably reduced the general quality of the total gas production. Should standards be further reduced, the process might show more marked economies.

HEAT FLOW IN COAL

In connection with a study of the flow of heat in coal, being made by the Bureau of Mines at its experimental coal mine near Pittsburgh, Pa., the problem of determining the rate of flow of heat from the ventilation air into the coal at the experimental mine has been attacked by making use of a standardized flow plate inlaid in the coal walls of the mine. This plate consists of a sheet of lead ¾ of an inch in thickness and three feet in diameter. Thermocouples mounted in the opposite faces of this plate enable the operator to determine the temperature gradient across it, and, knowing the thermal conductivity of the lead, the quantity of heat flow into or out of the coal follows immediately. The conductivity of the coal is also computed by using these data, together with the temperature gradient in the coal. This gradient is found by means of a large number of thermocouples which are located at various positions in the mine wall.

The Operators' Point of View

HOW MUCH FUEL DOES A CLEAN BOILER SAVE?

By W. F. S.

Here is an interesting and valuable chart for finding the fuel saved by keeping boilers clean. Simply zigzag across the chart three times with a straightedge or fine black thread, as indicated by the dotted lines drawn across, and the per cent. of fuel saved is found in the last column at the right—Column G.

For example, if the temperature of the chimney gases before cleaning was 580 deg. F., and after cleaning 480 deg., and if the heat value of the coal is 12,000 b.t.u. per pound, what is the percentage of fuel saved?

Connect the 580 (column A) with the 12,000 (column C) and make a note of the figure intersected in column B. In this case we find the figure in column B to be 70 per cent. Now begin at the 12,000 (column C) and run a line through the temperature difference (before cleaning and after) in column D, which is easily figured to be 100 deg. Continue the line until it intersects column E. Column E, you will note, is intersected at 3.8 per cent. Now from this point (column E) run through the figure in column F, which is the sum of the figures obtained in column B and E. In this example the sum is (70 plus 3.8 per cent.) 73.8 per cent. The continuation of this last line through column G gives the answer as 5.15 per cent.

The instructions on the chart itself tell just what to do as you go along. Each column is fully explained, excepting column B and E, which are to be added together for use in column F. In zigzagging across, the second line from column C to column E begins where the first line ended—at the 12,000 b.t.u., the 13,000, or whatever it happens to be. In this example it is 12,000 b.t.u. In the same way the third line, from column E to column G, begins where the second one ends. The writer has experimented with this chart to find which is quicker—the chart itself or the formula on which the chart is based. In every instance I found the chart to be much quicker. The only mathematical operation involved—adding two simple numbers—requires very little time or thought and can frequently be done mentally.

Not long ago I developed and published a formula for computing the fuel saved by cleaning boilers. This formula met with considerable approval. One correspondent, however, asked if I could alter the formula and get rid of the "boiler efficiency factor" which was contained in the formula. Many operators of boilers haven't an inkling regarding their boiler's efficiency, and as soon as one begins to talk efficiency to them they shrug their shoulders and give up the task as hopeless. With this correspondent's suggestion in mind I sought out some good representative steaming tests where I knew the firemen and engineers did the best they could and derived this formula:

$$\frac{100\,(T-t)}{0.22H-0.37T-t} =$$

Per cent. of fuel saved, assuming 18 pounds of air per pound of fuel.

Where

T=the temperature of the chimney gas before cleaning;

t =temperature of chimney gas after cleaning, deg. Fahr.;

H=heat value of fuel in b.t.u. per pound.

This is the formula upon which the chart is based. It contains three most important factors, all of which are usually known or determined without great effort. T and t can be found by means of a pyrometer or a thermometer properly placed in the gases. If a thermometer is used don't place it close to any comparatively cool body or the bulb will radiate heat so rapidly as to affect the reading considerably. The heat value of the coal, H, can be ascertained with fair accuracy from Bureau of Mines publications, which list the heat values of coals mined all over the United States. Naturally the chart is subject to criticism. It is not claimed to be perfect. No boiler efficiency formula can be expected to be perfect, containing only three factors, as this one does. It is simple, however, and that is a thing that is always wanted. It shows clearly that a cleaning operation should reduce the temperature as much as possible. The lower the final temperature the better. It also shows that it is desirable to use high-quality coal—coal of high heat value. The lower initial temperature and the higher heat value of the coal, the more difficult it is to save coal, because under such conditions the efficiency of the boiler is already high.

The range of this chart is great enough to include most boilers. The efficiencies range from 50 to 100 per cent. The maximum temperature decrease is 200 deg. F., which is sometimes exceeded but seldom is an average decrease. Column G shows that the chart will compute savings all the way from 2 to 15 per cent. Should your problem be so unusual as to fall outside of this chart, which is improbable, recourse may be had to the formula which is given above.

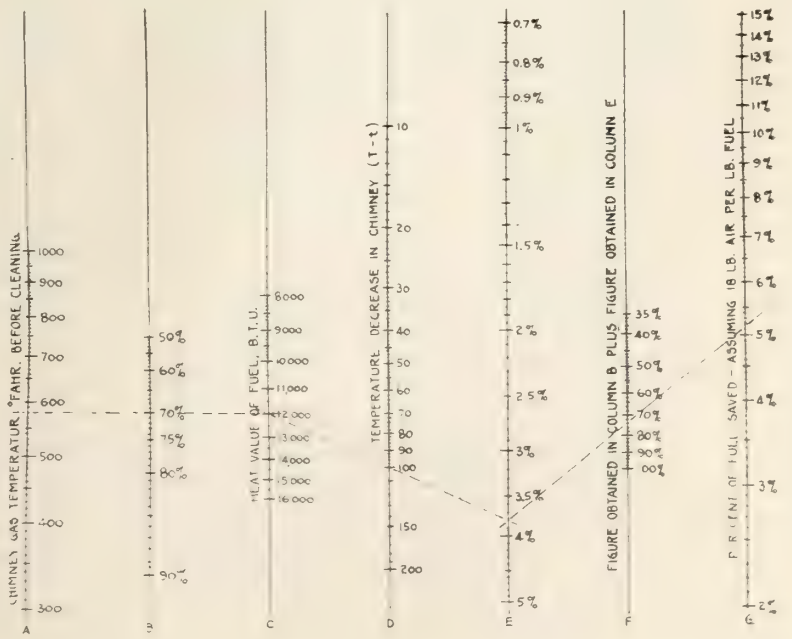


Chart for finding the consumption of fuel.

Requirements of a Good Bearing Metal

THE relative value of a bearing metal is not to be judged by its composition and physical properties alone. Many other factors, which are frequently overlooked, should enter into its selection. For instance, the lower specific gravity of the tin-base metals, and the fact that they can be used to advantage in very thin linings, should make them the logical selection for many bearings in which a lead-base metal is now used.

Again, allowance is very rarely made for the losses which occur in the melting and remelting of many metals. A babbitt of properly balanced composition, which is carefully alloyed from strictly virgin materials, should give very little dross and be remelted without serious loss of either metal or properties. Unfortunately, however, the use of virgin materials in the manufacture of babbitt is the exception rather than the rule, and any apparent saving recoils heavily on the head of the purchaser. The loss in melting babbitts made from reclaimed metals is frequently as much as 6 per cent. This item alone, with a fair allowance for melting cost and overhead, increases the actual cost of the metal by fully 10 per cent., to allow nothing for the sacrifice of bearing properties inevitable to the substitution of reclaimed for virgin metals.

While it is difficult to secure bearings of perfect uniformity from babbitts alloyed in the customary manner, the difficulty is magnified a thousand fold when reclaimed metals are used, and if the purchaser is buying bearing service rather than so many pounds of metal he does not get what he pays for. In service, the most obvious, but by no means most important, requirement of a babbitt is that it should have sufficient strength and hardness to carry the load with a reasonable factor of safety. The physical properties of a babbitt are valuable only in determining that it will meet this requirement and it should be borne in mind that they normally give very little, if any, indication of the performance of the metal in other respects. The compressive strength and Brinnell hardness tests do, however, serve as an excellent guide to the uniformity of metals of the same analysis.

The tensile strength and elongation of a metal are valuable as indicating its ability to withstand repeated shocks and pounds without cracking or fracturing, and are more important than the compressive strength and hardness in metals which are to be subjected to a pounding action or are to be poured into very thin linings. It is when abnormal conditions are encountered that the true requirements of a babbitt become apparent. In the majority of machines the bearing surfaces are normally separated by a film of oil, and were this condition to continue indefinitely, sufficient strength to carry the load would be the sole requirement of a bearing. There is, however, as will be discussed later, an ever present liability to separation of the oil film which cannot be foreseen or prevented. This breakage of the film may be due to many causes; temporary or permanent failure of the oiling device, the introduction of foreign matter, heavy overload, etc.

Immediately the oil film breaks, the journal and bearing come into contact and heat is generated due to the friction. How soon this heat may become sufficient to cause failure of the bearing depends entirely upon the true bearing properties of the babbitt. As in ninety-nine cases out of one hundred the separation of the oil film is temporary rather than permanent these properties are of extreme importance. It will be realized from the above that the metal is best which most fully combines the following properties:

(1) A tendency to hold the oil film when extraneous conditions are tending to separate it.

(2) A low coefficient of friction, to reduce the quantity of heat generated.

(3) Relatively high heat conductivity, to more rapidly convey the heat from the point at which it is generated.

(4) Ability to continue to carry the load at abnormal temperatures.

A consideration of the requirements outlined above is as essential to the intelligent selection of a babbitt as its more obvious physical properties, and they are even more deserving of the attention of the engineer.

THE HUMAN EQUATION

By John Scotch

Tell the average man upon the street that a certain steam boiler has had a new safety valve attached to it and he is convinced this boiler is protected against explosion. The dangers of the power plant, operated by steam pressure, have been brought to the attention of the public on numerous occasions without leaving any impression. They do not realize that a safety valve is one in name only unless it is large enough to carry away the steam as fast as a boiler can generate it, and that it is always in perfect condition to operate.

About the most reliable safety machine in a power plant is a careful, capable engineer. With a careless and inexperienced engineer in charge all mechanical safety devices can degenerate through neglect or ignorance into devices of danger. No fool-proof safety device has ever been made for the power plant although there are many so called ones. I have always held the opinion that in the examination of engineers for certificates the most important points should be the character and reputation of the applicant as an engineer. In a great many examinations the applicant is compelled to give a list and description of the plants he has been employed in. I venture to state that very often his unsupported statement is taken in the matter, and that no real effort is taken to verify his statements. I knew a man who passed an examination and secured a certificate (not in Ontario under the present Act) by answering the questions, and he had been employed in a power plant for some years. This man told me later that the only work he had done for the power plant was to deliver wood to it. Because a man has worked in several large plants totaling some years does not mean that he is a safe man. Proper investigation might show that his experience and knowledge would count as little against his many defects such as laziness, carelessness, lack of human understanding, etc. The man in charge who, to use a slang expression, gets the goat of his helpers, is a dangerous man so far as securing the best out of workers is concerned. It matters little how much knowledge he possesses along other lines. A man who has much less mechanical knowledge but who is faithful to his employer and can get the whole-hearted support of the men under him is in my opinion the safer man of the two. The educated man can save his employer money by his expert advice when new equipment is to be bought or installed and in other ways, but there are quite as many ways he can cause his employer to lose money, unless he secures the faithful co-operation of the men under him.

CARE OF GAUGE GLASSES

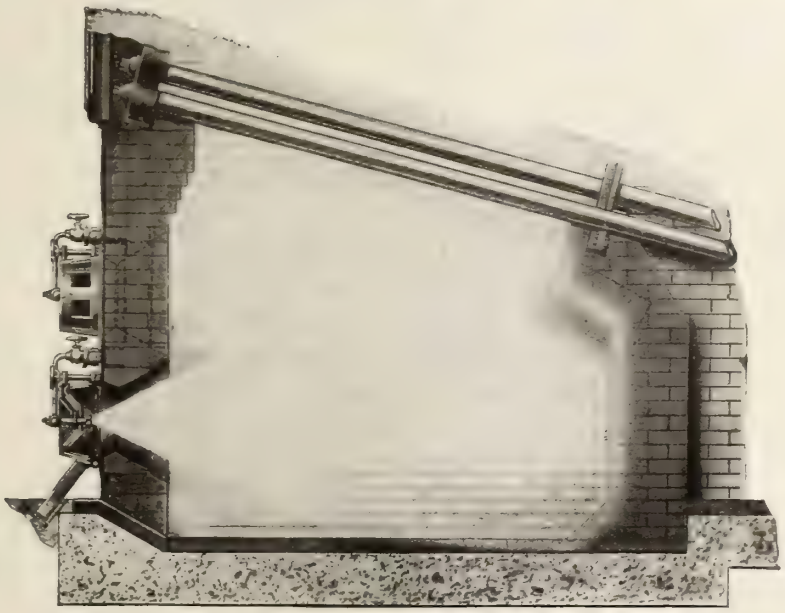
By J. James

Gauge glasses are an important item in the power plant. It is strange therefore how careless some men are in storing them, even hanging them up by running a wire through them. When it is considered how sensitive the interior of such glasses are it is not to be wondered at that when treated so roughly they break quickly in service. I have seen gauge glasses bare of covering dumped into a box and every time the box was moved, which was every time anything else was required out of the cupboard in which the box was kept, it was roughly pushed aside. This would make the glasses roll around against and over each other. When storing gauge glasses each glass should be carefully wrapped in paper to prevent them coming in contact with each other or any hard material. Note how such glasses come from the dealer. They are wrapped tightly in paper.

Some men advise leaving the water in gauge glasses where no night man or watchman is employed. Numerous instances have been recorded where a glass has broken during the night, and often such plants have the fires banked at night, a small steam pressure being carried to supply heat for some purpose. Imagine the result of a broken glass in such a case. Perhaps thousands of dollars worth of damage done to goods. The

BABCOCK & WILCOX

OIL BURNING EQUIPMENT



Babcock & Wilcox furnace for burning oil fuel only

The merits of oil as a fuel for steam generation, in places where its cost compares favorably with coal or wood, are, briefly, the following:—

1. An increase in boiler efficiency, owing to the clean condition in which the boiler heating surface can be maintained, and the completeness of combustion obtainable with a good system of oil firing.
2. A constant and equal distribution of heat in the furnace, and, as there are no fire doors to be opened, the cooling effect of a large volume of air passing over the furnace is avoided.
3. A reduction in the cost of handling the fuel, as this can be done by a pump; and a large reduction in manual labor, the firemen not being required as they would be for ordinary fuels. One man can regulate the burners of a considerable number of boilers.
4. No wear and tear of grate bars.
5. No dust, no ashes, and no clinker.
6. When once arrangements have been made, the storage of oil fuel is simpler than the storage of coal, and oil does not deteriorate.
7. The control of the steam production is easier, more effective and more rapid than with solid fuels.
8. Instantaneous ignition, and extinction of the fire.
9. No smoke.

The three main systems for burning oil fuel are:—

1. That in which STEAM is used as a spraying or atomizing agent.
2. That in which AIR is used for this purpose.
3. That in which the oil is atomized mechanically by PRESSURE.

We would be glad to go into details with a prospective purchaser.

HEAD OFFICE FOR CANADA - COLLEGE ST. (ST. HENRY), MONTREAL

TORONTO OFFICE, BANK OF HAMILTON BUILDING

dead reason advanced for leaving water in a glass at night is that some fireman might start a fire and forget to open the gauge glass valves. Any man who will break and limber up a banked fire without first looking at the glass and making sure the water is o.k would be either full of home brew, a fool, or a man ignorant of power plant work. Such a man would be all right throwing in cordwood to burn bricks in a yard. Gauge glass cocks are in the same class as water column cocks in one respect anyhow, they should be tested often.

PULLEY AND GEAR SIZES

By F. C. M.

After careful reading of article re Lever Pulleys and Gear Drives, I might offer a more simple formula to determine different speeds as, in my estimation, the knowledge of algebra is not necessary. All that is required is the knowledge of multiplication and division.

The following rule has been followed by the writer during his forty years' experience on construction work, and has never resulted in a mistake on speed, both on pulleys and gears.

For gears we may take the pitch diameters and figure them the same as pulleys but the more accurate way is to multiply the number of cogs on the driver by the revolutions of the shaft and divide by the number of cogs on the driver. It amounts to the same thing but seems to me a much simpler way.

The same rule is applied on pulley drive. Multiply the diameter (in inches) of the driver by the number of revolutions and divide the product by the diameter of driver, the result of which will be the speed of same, or if a desired speed is required, multiply the diameter of driver by the number of revolutions and divide by the number of revolutions required, hence the size of the pulley.

Re quarter-turn or right-angle drives, an invariable rule which is very simple is to set the two discharging centres in line, or plumb if a vertical drive.

MAKING MISTAKES

By J. Gelethorne

A week or two ago a chief operating engineer became acquainted with my son while attending the Toronto technical school. He informed my son he had read a number of my letters and articles in Power House and other technical journals, and that he had noted ideas and suggestions in some of these articles which he considered not altogether correct according to his point of view. It is quite possible his point of view is right and mine wrong. I have written hundreds of articles for publication during the past twenty years and I would be an engineering superman if some of these articles did not contain flaws. The Editor of an engineering journal would be one of the wonders of the world if no mistakes got past him and into print. There is one man I would imagine the editor is always pleased to have a letter from, that is the lad who notes some mistakes or misstatements printed in the journal and directs the editor's attention to it thus giving him a chance to put the matter right with his readers. Apparently trivial mistakes can cause a lot of trouble, and especially so in engineering. A writer should be very sure of his case before he submits it for publication. The serious misstatements seldom get past the editor's observation, but he is only human like the rest of us and has to relax sometimes. It appears strange but seems true, whether in engine or editorial room. Fate uses these moments when we cease to be alert to put something over on us, probably fate is doing us a good turn in a left handed way. When we are notified about these mistakes it has a tendency to reduce our stock of self-conceit to its proper level. This illustrates the great benefit writing for his power plant journal is apt to be to the engineer. It teaches him to carefully investigate before writing or deciding, this is the reason you cannot teach others without teaching yourself.

RE ENGINEER'S LICENSES

The Editor, "Power House,"

Sir:

Could you spare me a few lines of your paper to enquire as to the following:—What class of papers does it take to operate a heating system, say for instance, a 75 h. p. r. t. boiler carrying 10 or 15 lbs of steam? I would like to inform my brother engineers that there are lots of heating systems in Toronto that are being operated by men without certificates. Should a man be allowed to operate a steam boiler and do the general work around a plant and defy all law? Why not have inspectors the same as they have for anyone carrying a bottle of liquor on the street? The laws are all made by the same people, and who is supposed to see that the law is enforced? I was talking to a man the other day who has charge of a building in the centre of the city of Toronto, and he had no Ontario license to operate a boiler. He said he had an Ohio paper that was better than a chief's here. Now could an engineer from Toronto go to Ohio and tell the engineers in America that he had a ticket superior to theirs and get away with it? Yet the unions and the C. A. S. E. are giving educational classes to improve the engineer, and the ones that are really keeping the office at the top of Spadina are the ones to pay for it all, and yet anyone can get an engineer's job in the city for heating buildings and sprinkler tanks without a license of any sort. I may seem a little pessimistic, but if needs be I can show you lots of engineers out of a job, that have paid for their certificates, and as long as they keep paying their renewal every year, and as long as there is enough paying to keep those fellows in their jobs, they have no need to worry.

SECOND CLASS ENGINEER.

We publish the above letter not because we in any way agree with the writer, but simply because if we did not publish it, the writer would feel that his complaints are so well grounded that he could not get fair play, etc. From our personal knowledge we know that the Board of Examiners are doing all that is humanly possible to carry out the law, and if any man knows of an instance where it is being violated, it is his duty to bring it to the attention of the Board. It is a considerable time since we have heard any complaints such as the above, though at one time they were very frequent. We attribute the decrease to the fact that the engineers in the province are becoming acquainted with the work the Board is doing. As a matter of fact the writer of the above should know that where the pressure carried is below twenty pounds per square inch no certificate is required by law. The wisdom of this may be open to question, but the law is as it stands. We would advise our correspondent to go up to Spadina Avenue and have a talk with the gentlemen connected with the Stationary Engineers' Board, and we guarantee he will come away with a much better opinion of them and their work than he seems to have at present. —Editor.

A bulletin has been issued by the Laclede Christy Clay Products Co., St. Louis, describing the installation of the Laclede Christy stokers in the Kansas City plant of Armour & Co. The booklet contains a number of illustrations, and complete performance data is given, which should be of interest to stoker users in general.

The Reliance Gauge Column Co., have disposed of the Cleveland Clutch business to the Western Engineering and Manufacturing Co., 360 Grand Avenue, Chicago, and will devote their energies in future entirely to the manufacture of the steam specialties with which they are identified. These include safety water columns, steam traps, seamless floats, etc.

SPONTANEOUS COMBUSTION OF COAL

At the Pittsburgh, Pa., experiment station of the United States Bureau of Mines, J. D. Davis, fuels chemist, and J. F. Byrne, research fellow, Carnegie Institute of Technology, have investigated the relative tendency of Pennsylvania coals to ignite spontaneously. The research consisted largely in the development of methods for the determination of the comparative sensitivity of coals to oxygen. A study was made of the comparative sensitivity of coal constituents of oxidation in co-operation with Dr. H. Thiessen, research chemist, the coal constituents being separated by the aid of a microscope.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

EDUCATIONAL FEATURES STRESSED IN POWER EXPOSITION

The National Exposition of Power and Mechanical Engineering will open at 1.00 p.m. on Thursday, December 7, 1922, at the Grand Central Palace. It will immediately follow the annual meetings of the American Society of Mechanical Engineers and the American Society of Refrigerating Engineers and will remain open until December 13th, except on the intervening Sunday.

This exposition will be the first large scale attempt to display mechanical and power plant apparatus so that the present extraordinary state of development will be apparent not only to the highly trained technical man but to the layman with little knowledge of the severe problems involved in the engineering design and operation of combustion apparatus and power generating machinery. A very small percentage of the individuals in the world are informed about the tremendous importance of the enginering arts and sciences to our present civilization.

The advisory committee of the Power Exposition realizes thoroughly the need for greater public information and understanding of the engineering problems of the day and therefore it has set aside a large centrally located space at the Exposition and here will be shown models of the various devices that enter into the process of taking coal from the mine, handling it as the power plant, turning it to steam, using the steam to generate electric power and sending the current out through wires to the consumer.

As an excellent example of the manner of preparing anthracite coal for the market, the model of the famous Loree breaker of the Hudson Coal Company will be exhibited. This model, requiring an entire express car for shipment to the exposition, is a replica of the largest breaker in the world, which was erected and put in operation in 130 days and in 1921 handled 591,000,000 tons of coal. This model will show the breaker in operation, crushing the large lumps of coal, sizing it through screens and passing the sized coal through jigs where the refuse is separated out.

The development of the power station itself will be illustrated by the exhibition of a series of models of the important central stations in New York City. The original station erected by Thomas Edison in Pearl Street will appear beside the more modern Waterside Stations and the recent Hell Gate Station. The representation of this latter station is a faithful reproduction built to a scale of one-quarter of an inch to the foot. It shows the steam and electric apparatus in the plant and the various boiler room and turbine room auxiliaries as well as the elaborate machinery for handling the enormous tonnage of coal and ashes.

To further enhance the educational and informative value of the exposition each of the exhibitors will demonstrate the fundamentals underlying the operation of their apparatus by simulating actual operating conditions as nearly as possible in their exhibits. If practicable apparatus will be shown in motion, otherwise complete diagrams will be displayed.

Visitors to the Exposition will not only include members of the A. S. M. E., the A. S. R. E. and the A. S. S. E. all of whom are holding meetings during the few days preceding the meeting, but all members of engineering societies who have problems relating to power and mechanical engineering will be admitted on presentation of their membership cards. The societies who have been invited to the Exposition are: Stoker Manufacturers Assn.; American Institute of Electrical Engineers; American Economic Association; American Society Civil Engineers; American Institute of Mining and Metallurgical Engineers; Society of Industrial Engineers; Society of Welding Engineers; American Society Heating and Ventilating Engineers; National Electric Light Association; and Building Managers and Owners Association.

Realizing the great importance of the Exposition to the operating engineer, the National Association of Stationary Engineers is organizing to attend the exposition in groups. The New York Building Superintendents Association will also attend in a body, as will the Technical Publicity Association and the Blue Room Engineering Society of New York.

The Committee which is guiding the Exposition consists of Irving E. Moultrop of the Edison Electric Illuminating Company of Boston, Chairman; Dester S. Kimball, President of the American Society of Mechanical Engineers; Alexander G. Christie, Chairman Power Division A. S. M. E.; Fred Felderman, National President National Association of Stationary Engineers; Milan R. Bump, Past-President National Electric Light Association; N. A. Carle, Vice-President Public Service Production Company of New Jersey; E. B. Katte, Chief Engineer Electric Traction N. Y. C. R. R. Company; Fred R. Low, Editor "Power;" David Moffat Myers, Consulting Engineer; Calvin W. Rice, Secretary The American Society of Mechanical Engineers; and the Managers, Charles F. Roth and Fred. W. Payne, with offices in Grand Central Palace, New York.

One Ton or a Shovelful?

One man can raise a ton with the **Godfrey Conveyor** and not exert a fraction of the energy required to lift a shovelful of coal. He unloads a carload in 1½ hours at an average power and labor cost of from 5c to 7c per ton. When you realize that this equipment costs no more than a good truck, you will want to know more about it. Ask for Catalog D.

PATENT NOTICE.

To all whom it may concern:—

Be it known that CHARLES PRACHE, of Paris, France, is willing to license any Canadian manufacturers under his Canadian Patent No. 203,025, for EVAPORATOR.

Further information may be had by applying direct to me, or to Messrs. Marion & Marion, 364 University Street, Montreal. P.2.H

FOR SALE

BURNHAM STEAM PRESSURE PUMP, 10 IN. x 1⅛-inch. x 12 in., nearly new, with Fisher governor attached. W. Ahearn, 538 McLaren St., Ottawa. When answering this advertisement please mention this paper. P.F.H.

I.H.C. 12 H.P. GAS ENGINE FOR SALE—ALL in good running shape, with 33-inch clutch pulley; will be sold reasonable on easy terms. Apply W. Harrison, & Son, R. R. 5, Guelph. When answering this advertisement, please mention this paper. P.F.H.

ABSOLUTE BELTING BARGAINS—BELTING every description; rubber hose, thresher supplies, tank pumps, pump leather feeds, canvas, McGill auto powers, special reduced prices; for quality and price, you can't beat us. N. Smith, 134 Adelaide west, corner of York, Toronto. When answering this advertisement, please mention this paper. P.F.H.

TAYLOR SAFES FOR SALE—RARE OPPORtunity to secure a safe at small cost. They are in splendid condition. Inside dimensions and prices are as follows: 15" deep, 2 ft. 6" wide, 3 ft. 11½" high, fitted with built-in compartment. Price $250.00. 18" deep, 2 ft. 8" wide, 4 ft. 5" high, fitted with steel compartment. Price $200.00. Apply Box 10, POWER HOUSE.

MISCELLANEOUS

THE JOHN INGLIS CO., LTD., ENGINEERS and boilermakers. Write us for prices. 14 Strachan Ave., Toronto. When answering this advertisement, please mention this paper. P.F.H.

ELECTRICAL CONTRACTING AND MOTOR repairing. Leslie Electric Co., 74 Grange Ave., Toronto. Phone College 490. When answering this advertisement please mention this paper. P.F.H.

POSITIONS VACANT

BRITISH INSTRUMENT FIRM REQUESTS applications for position of Travelling Salesman. Knowledge of Power Plant and Civil Engineering Instruments and accessories. Write stating age, experience, and salary required to Box 100, Power House.

Every Engineer, Mechanic and Electrical Worker will welcome this new master set. It will answer your problems.

It will help you with your daily work.—A sure source of advancement and higher pay. Complete up-to-date information that is thoroughly and easily explained on every branch of modern engineering and electrical practice.

AUDEL'S ENGINEERS & MECHANICS GUIDES
4750 PAGES **8754 ILLUSTRATIONS**
$1 A MONTH **$12 COMPLETE**

These Guides tell you all about—

Theory, Practice and **Operation** of ALL Steam Engines; UNIFLOW and POPPET VALVE ENGINES, and LOCOMOBILES. Locomotive-Marine Engines; Turbines; Rotary Engines --the Indicator -- Lubrication -- PRACTICAL MANAGEMENT. GAS, GAS ENGINES--*Aeroplanes* and *Aviation*--HOW TO SELECT AN ENGINE. STEAM ENGINE rules and formulae. Steam Boilers; Heat-Combustion; Fuel and Flue Gas Analysis-C02 Recorders-Construction of all types of Boilers,--Mechanical Stockers--Oil Burners--Setting--Chimneys--Mechanical Draught --HOW TO SELECT A BOILER. BOILER DESIGN based on A.S.M.E. BOILER CODE--OPERATION FIRING. Pipes, Fittings--Heating and Ventilation--Refrigeration--Cooling Towers --Condensers--Distilling Apparatus--Elevators--Cranes--Ropes and Cables--Splicing--*Practical Electrical Engineering* as an aid for engineers and electricians in obtaining a license--ready reference index, covering entire field of Modern Electricity.

SHIPPED TO YOU FREE

Not a cent to pay until you see the books. No obligation to pay unless you are satisfied. Send coupon now--today and get this new master set for engineers. Pay only $1 a month.

SEND NO MONEY

THEO. AUDEL & CO, 72 Fifth Ave., N. Y.

Please submit me for approval, AUDEL'S $10,000 MASTER SET FOR ENGINEERS & MECHANICS. Ship at once prepaid, the 8 numbers. If satisfactory, I agree to send you $1 within 7 days and to mail you 1 monthly until $12 is paid.

VIMY

Better Work in Quicker Time

Just the right heat all the time—no waiting. Absolutely dependable—fully guaranteed.

THE VIMY SUPPLY CO., 576 College St., Toronto, Ont.

MONCRIEFF'S

Moncrieff's "Unific" is not a cheap glass. But because it outlasts many ordinary glasses the "Unific" is economical. British Made.

"UNIFIC" WATER GAUGE

JOHN MONCRIEFF LIMITED
PERTH, SCOTLAND
Canadian Representative: W. J. WALL, 134-136 Bleury St., MONTREAL, CANADA

GLASSES

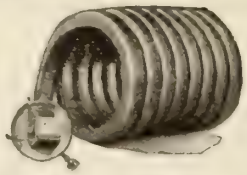
The "Unific" does not readily corrode. It resists extreme changes of temperature and withstands the highest working steam pressure.

A COMPLETE SERVICE IN

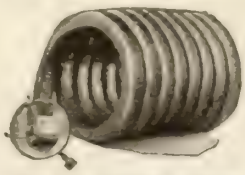
"John Crane"

FLEXIBLE METALLIC PACKING

Style 100 [illegible]



Style 400 — Resilient duck channel with flexible metal [illegible] wearing face



Style 300 Resilient asbestos [illegible]

Style 104- Slow speed ammonia sets (comb. of cut rings of [illegible] and 400)

Engineers are finding truer economy and greater service in John Crane" styles 100, 300 and 400 used alone or combined, than [illegible] any other offerings in packings.

Style 100 gives minimum expansion.

Styles 300 and 400 yield maximum expansion.

Combinations arranged in the judgment of the engineer provide for intermediate requirements.

Write for complete catalog. Furnish stuffing box dimensions.

HEPBURN PUMPS

Self Draining

For boiler feed or vacuum service

The long strokes of these Hepburn pumps give an efficiency not attainable with short stroke pumps. The simplicity of the Valve Gear and the small number of working parts make it a most desirable pump for all purposes. The Steam Chest, being located on the side of the cylinder instead of on the top, the main steam ports enter the lower side of the cylinder bore. Consequently, all condensation is drained away to the exhaust port at every stroke of the piston, thus preventing water hammer in the cylinder and making drain cocks unnecessary.

Shall we send you a catalogue to look over?

A Striking Message

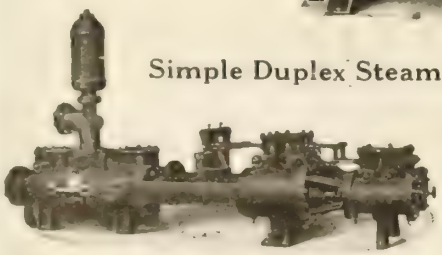
A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. Here is the letter:

"I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. **This is a mistake on their part,** but for all I know to the contrary it may be due to the lack of energy on the part of the Power House ad. manager in getting after them. **It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages SO MUCH AS ON THE ADVERTISEMENT PAGES."**

The
John H. McGowan Co.
Cincinnati, Ohio, U. S. A.

Builders of Pumping Machinery

Our 70 years' experience in designing and manufacturing pumping machinery places us in a position to analyze any situation and make recommendations as to the type best suited for same.

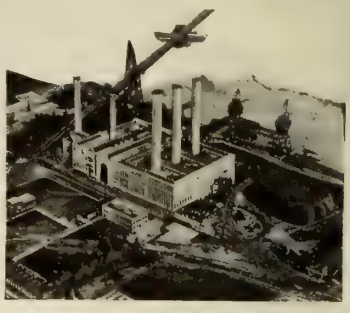


Simple Duplex Steam Power for all conditions of Service.

You are sure to
BUY RIGHT
if you profit by the experience of the LARGE CENTRAL STATIONS

Their very existence depends upon how cheaply and efficiently they can generate steam. Naturally every bit of boiler room equipment they buy must be the best of its kind.

In line with this policy, their engineers have made careful comparisons of all types of boiler feed water regulators. It is worth noting that **98 per cent. of the leading Central Stations use the COPES System of Boiler Feed Water Regulation.**



Consolidated Gas, Electric Light & Power Co., Baltimore, Md. A well-known COPES user.

There are many good reasons for this: One of them is the COPES' simple and rugged construction—just a heavy metallic tube and a balanced valve. No springs or diaphragms, to weaken and impair accuracy; no floats or displacement bodies to cause "lag."

Other advantages of COPES Regulation are interestingly described in Catalog D—the COPES method of changing the water level according to every change in load—the fuel savings that result (COPES users report 2 per cent. to 8 per cent.)—and other features which mean higher boiler efficiency.

A TYPE FOR EVERY PURPOSE

And Service 'way beyond the average!

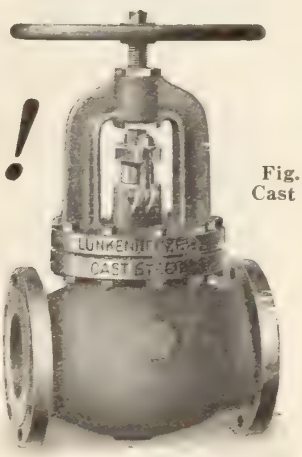

Fig. 606
Cast Steel

Be it a small size water or oil line, or the large size high pressure and high temperature steam line, there is a Lunkenheimer Valve especially suited to the purpose. Every type is designed to give maximum service under extreme operating conditions, and with the line complete, standardization throughout the plant, with its many advantages, is easily accomplished.

With seating surfaces regrindable and all parts made to gauge and renewable, the installation of Lunkenheimer Valves means permanence in the line with a minimum expense for maintenance and repairs.

Our catalog No. 58-DC illustrates and describes the various types in detail. A copy will be sent on request. If you have a valve problem, we will help you—no obligation.

LUNKENHEIMER
Blow-off Valves

Remain tight in service, prevent waste through boiler blow-off lines, and thereby turn to a profit the losses caused by leakage which frequently occurs at this point.

In Lunkenheimer Blow-off Valves the water is released gradually, due to the peculiar construction of the seat and disc. This virtually makes them safety devices since they eliminate the dangers incident to undue agitation within the boiler or severe shock in the discharge line which result when blow-off valves are opened suddenly.

Lunkenheimer design and construction reduces wear to a minimum. When wear does appear the repair of the parts affected is easily accomplished and when a part is worn beyond repair it can be renewed.

The installation of Lunkenheimer Blow-off Valves is the solution of your boiler blow-off problem. Why not get the facts first hand?

They Called It A Waste of Time

When we announced, years ago, that every inch of leather used in the making of **D. K. McLaren's Belting** would be subjected to the

Genuine British Oak Tanning Process

the statement was not taken seriously. It was thought that the process (while admittedly without an equal) would prove too expensive in application to the manufacture of belting.

Time has proved, however, that this one-time closely guarded secret process has more than justified the extra expense of tanning. It not only adds to the original toughness of the hides but it imparts a remarkable flexibility and stretchless quality that gives to **D. K. McLaren's Belting** a "gripping power" that means real "service on the pulley."

The Oak Leaf is stamped upon D. K. McLaren's Belting as a guarantee and as a guidance to engineers who have learned to appreciate trouble-free belting service.

Boilers For 1923

Many a manufacturer could pay a dividend out of his coal pile if he went the right way about it. We mean that the very heart of his power plant—his boilers—are inefficient, out of date, always longing for the repair man—and cost far more than they should in coal expense and labor.

Our suggestion is—look into your boiler situation now. You can get from us new, modern, absolutely efficient boilers at very moderate cost, equipped with the National Hand Fired Stoker, if desired, that will be a delight to your operating staff and a very decisive factor in reducing your costs.

Interior of Power House, showing Breast Wall.

The left wall of the Power House interior is the inside of the Breast Wall which shows in the illustration on the left.

THE NASSAU POWER PLANT

of the

Canadian General Electric Company

At PETERBOROUGH, ONTARIO

This plant was constructed in connection with the reconstruction of the Nassau Dam by the Department of Railways and Canals. The first unit of the plant was put into operation in March, 1922.

The entire sub-structure of the Power House, including the forebay walls and draft tubes, is of concrete. It being essential that hydraulic losses should be reduced to a minimum, the draft tubes were finished with very smooth surfaces and well rounded corners.

The up-stream wall of the Power House is also the breast wall, and the interior of this wall is "bone dry," notwithstanding the pressure of the full head of 18 feet of water on the up-stream side. This result was obtained without the use of any waterproofing materials, which furnishes evidence of the value of concrete construction wherever a waterproof structure is required.

The Power House sub-structure was carried out in conjunction with the reconstruction of the Nassau Dam by the engineers of the Department of Railways and Canals, to the designs of Walter J. Francis and Company, the Consulting Engineers for the Canadian General Electric Company.

Coal is the least that a leaky steam trap wastes

By the time power gets up to your coils or machines as steam, it costs far more than at the coal pile, heat unit for heat unit. All along the line you are adding charges of firing, oiling, superintendence and overhead.

So to measure the loss from a leaky steam trap in tons of coal or units of power is not enough. This is a fact which drives home the importance of a steam trap worthy of the name.

"Just a ball—that's all!" A floating ball is the only moving part of the Johns-Manville Steam Trap. No valves, levers or thermostats to get out of order. And the action of this Trap, in preventing loss of steam and discharging air and water, is as sure as it is simple.

Why Johns-Manville Steam Traps do not leak

There is always, in a Johns-Manville Trap, a thin water seal between the steam and the outlet. Here is how this Trap works—and the extreme simplicity of its construction means that it always *does* work.

A hollow ball is the only moving part.

When the entering water raises the ball, the discharge orifice is exposed, and water and air flow out.

When the water level drops, the ball drops. It rolls over the discharge orifice, thus throttling down the outflow and maintaining sufficient water in the Trap to prevent steam leakage.

This action is sure. You can depend on the Johns-Manville Steam Trap to save power and so to help cut your operating costs.

SINCE 1864

On Great Engineering Projects

Following the hose and pipe lines from clanking rock drills, back perhaps to a shanty open to dust and dirt, we come to the throbbing air compressor.

The compressor rod packing forms an important item contributing toward successful and continuous operation. The intense dry heat of compression together with the abrasive action of grit and dust soon destroy a packing not designed for this trying service.

Garlock Style No 222 combination packing, designed with a thorough understanding of compressor requirements, has given efficient and continuous service on compressor rods under all conditions.

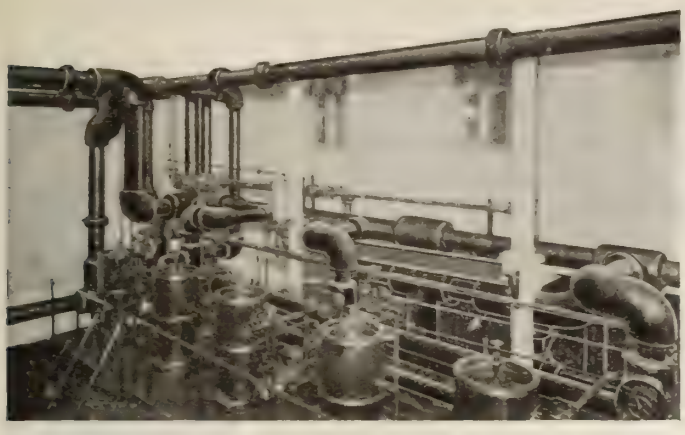
HAGERSTOWN MARYLAND, U.S.A.



Nonpareil Cork Covering on the ammonia lines and headers of the Abbott Ice Cream Company, Philadelphia, Pa.

COVERED

AND covered right. Every foot of pipe, every ell and tee and valve and union is so thoroughly protected by Nonpareil Covering that not a bit of frost shows anywhere. This is an excellent illustration of the *right* way to insulate brine and ammonia lines:

First—Insulate with Nonpareil Cork Covering because it is unquestionably the most efficient, durable and economical insulation made for cold lines; and

Second—Cover every square inch that needs insulation. Frost will form on exposed surfaces and damage your covering by working back under it.

Nonpareil Cork Covering saves 80% of refrigeration losses from uninsulated lines. 80% —that will pay the entire cost of the covering in less than a year, and there are records of Nonpareil Covering in service 20 years after it was installed.

The reason, of course, is that Nonpareil Cork Covering is moisture-proof and frost-proof. Properly applied and given reasonable care, it will not deteriorate. Actually, Nonpareil Cork Covering "Lasts Longer Than the Pipe."

Detailed information, samples and prices, will be furnished on request.

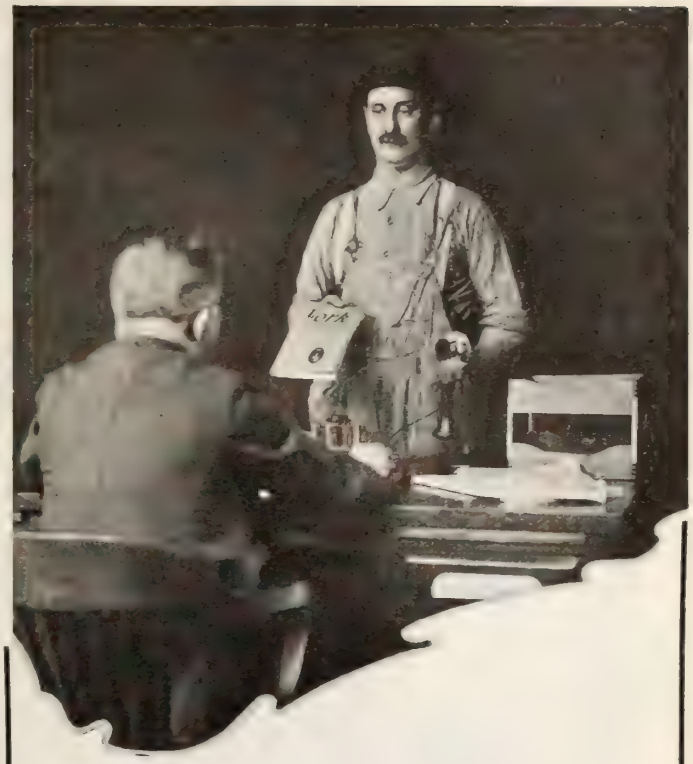
Armstrong Cork & Insulation Co., Ltd.

902 McGill Building, Montreal, Quebec
11 Brant Street, Toronto, Ontario

Also manufacturers of Nonpareil Corkboard Insulation for cold storage and constant temperature rooms and for settling tanks; Nonpareil High Pressure Covering for steam lines, feed water heaters, boilers, etc.; Nonpareil Insulating Brick for boiler settings, furnaces, ovens, etc.; Nonpareil Machinery Isolation for noisy machines, and Linotile and Armstrong's Cork Tile for floors in offices, residences, etc.

Nonpareil Cork Covering

For All Cold Lines



'For Reliable Service give me YORK Equipment"

When the Operating Engineer of an Ice Making or Refrigerating Plant insists upon the Plant Manager buying York Ammonia Fittings and Supplies, he knows he is saving himself a lot of time and trouble and also reducing the operating costs of the plant.

He knows, because he has learned through past experiences of his own, or perhaps from another Engineer, that York Equipment is designed and made to meet the severest Service.

Surely, the man who is responsible for the operation of the plant, who sees and handles the equipment every day, should be best able to judge the merits of each piece of apparatus.

And the engineer out of justice to his employers and to himself, will recommend York Apparatus, which he realizes will give satisfactory results in actual service. That's why more York Ammonia Fittings and Supplies are sold each year than any other make.

There is perhaps no other concern of its kind in the world able to handle such a large number of orders or such a heavy volume of business.

A trial order will convince you of the Superior Quality of York Ammonia Fittings and Supplies.

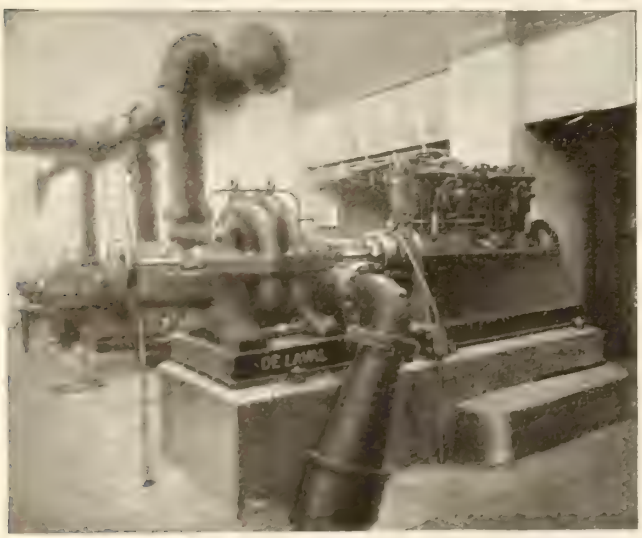
"The Drop-Forging People"

78 Thorold Road - St. Catharines, Ont.

ORILLIA, ONT., SELECTS DE LAVAL PUMPS FOR SAFETY AND ECONOMY



THREE DE LAVAL centrifugal pumps installed in the water works pumping station of the City of Orillia, Ont., are shown herewith. The two-stage 8-in. pump in the foreground is driven by a gasoline engine, and has a capacity of 1,440 gal. per min. against 325 ft. head. The two De Laval pumps in the background are driven by electric motors. Where cheap electric power is available, this type of plant combines low cost, simplicity, and insurance against shut-down. The amount of attention required is very small, and practically no supplies are used.

The De Laval centrifugal pump is ideally adapted for both electric motor and gasoline engine drive. The starting torque is low and the power characteristic permits the size of motor to be selected to suit the normal capacity, resulting in lower power factor and higher efficiency in the driving motor. In many instances De Laval pumps are driven by self-starting synchronous motors,-which can be used to correct the power factor.

State pumping requirements and ask for special publication B100.

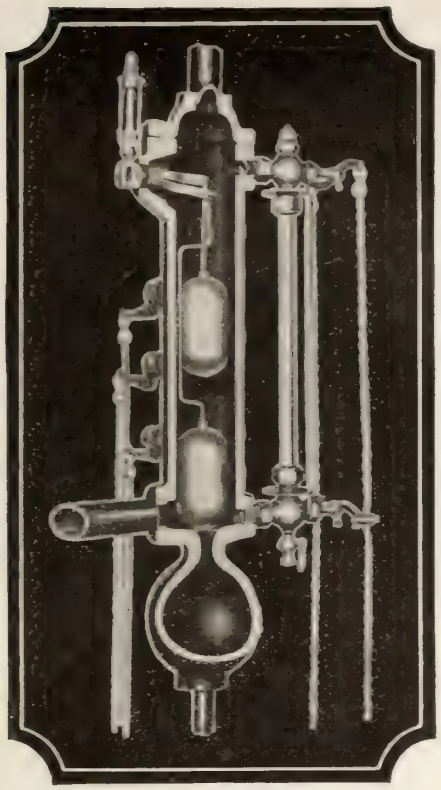
244

There is only one genuine Reliance Column and we have always made it. It has led its field for 35 years.



The working parts of a Reliance Column, shown here, are proofed against all kinds of wear or deterioration

honestly, now, is it all the fireman's fault when he has to pull his fires?

Loss, confusion and inconvenience are not the only unhappy results that follow when your fireman pulls his fires and the wheels stop turning.

There is always this embarrassing question to answer: "Why was the water allowed to get so low?" And though the answer usually places the blame on the fireman, is he altogether at fault? Being human, he's expected to slip occasionally.

But Reliance Safety Columns are not human; they do not slip. When the water gets dangerously low, they set up such a furious whistling that the fireman can't ignore them. He has plenty of time to avoid the necessity of pulling the fires.

Why have any fault at all? Install Reliance Columns.

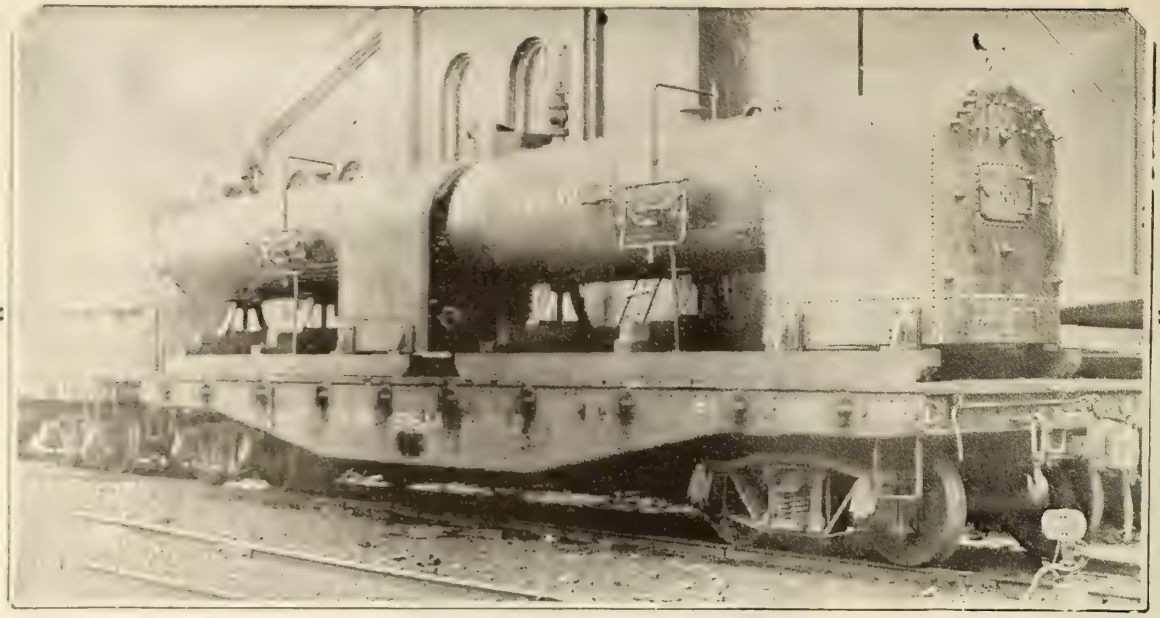
Have you written for your copy of our new catalog?

THE RELIANCE GAUGE COLUMN COMPANY

5936 Carnegie Avenue **Cleveland, Ohio**

Reliance

TRADE MARK REG. IN U.S. PAT. OFF.



Two 60 H.P. Locomotive Boilers for 125 lbs. Under Ontario Regulations.

E. LEONARD & SONS, LIMITED

Head Office and Works, London, Canada.

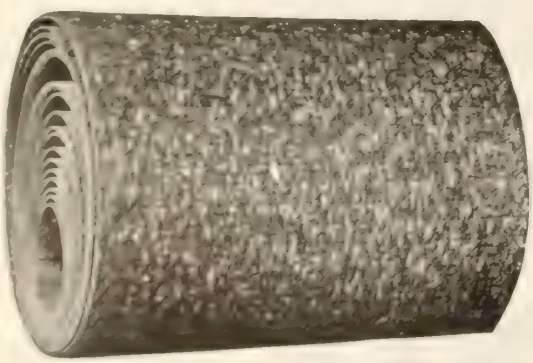
Branches and Agents from Coast to Coast.

Established 1834

LEONARD

DURABLA

NOW MADE IN CANADA



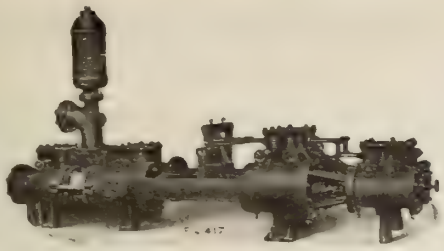
Durabla Sheet and Gaskets are now made in Canada by Canadian Durabla, Limited.

Guaranteed to make a tight joint wherever a permanent gasket is required.

Distributors:

The Canadian Fairbanks-Morse Co., Limited

Sales Offices in all leading cities.



The consumer whose service is interrupted "Can Hear No Excuse." Reduce complaints by using McGowan Duplex Steam or Power Pumps to handle your water service.

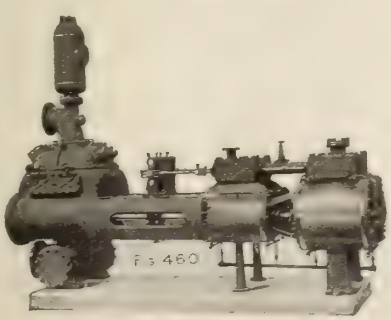
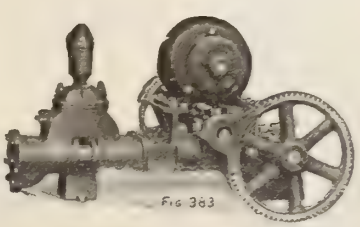
Every detail of our designs has been given the closest attention and the result of our 70 years in business brought to bear on same.

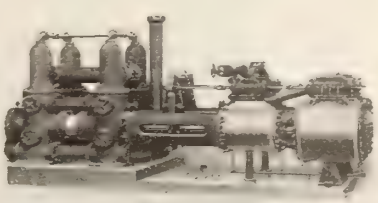
Every part is interchangeable.

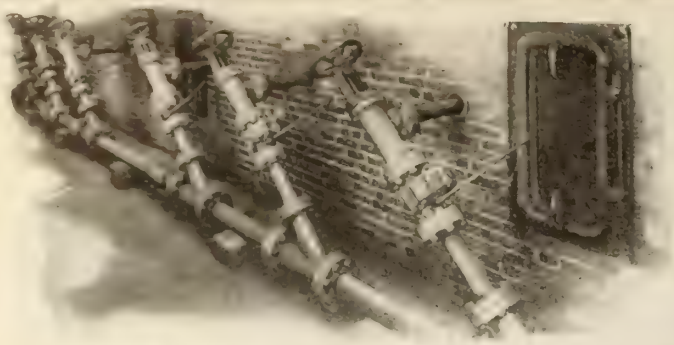
Every part is made to gauge.

Semi-Corliss Piston Valve

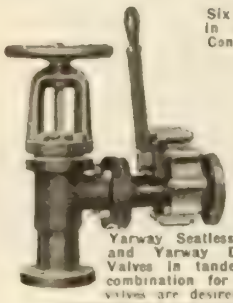






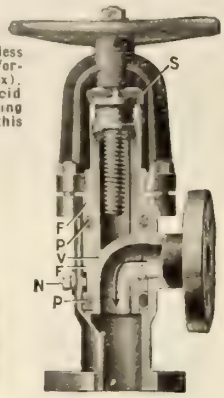


Six of the twenty-one Yarway Seatless Blow-Off Valves in service at the United Illuminating Co., Bridgeport, Conn.



Yarway Seatless Blow-Off Valve (formerly the Simplex). Send for celluloid model illustrating operation of this unique valve.

Yarway Seatless Blow-Off Valve and Yarway Double-Tightening Valves in tandem — the ideal combination for lines where two valves are desired.



YARWAY

Save More Steam for Useful Work with

YARWAY BLOW-OFF VALVES

There may be some ways of wasting steam that can't be avoided—but defective, leaky blow-off valves don't come in this class, even though they are so often overlooked.

There's no need to let your good fuel dollars run into the sewer through poor blow-off valves. YARWAY SEATLESS BLOW-OFF VALVES stay tight and keep the steam where it belongs; often for six, eight, ten years—and no repairs. That's not just our own say-so—we'll be glad to give you the names of users who have proved it for themselves.

When you buy the YARWAY, you take no chance. Others have done the experimenting; you get the benefit.

On the face of it, don't you think it would be worth-while to get the facts about these tried-and-proven valves? We'll send them promptly —just ask for Booklet B-410.

POWER PLANT DEVICES *to save fuel*

Diamond Valv-In-Head Soot Blowers

Eliminate the Human Factor

With Diamond "VALV-IN-HEAD" soot blowers the number of manual operations is very greatly reduced and opportunity for errors in those performed is extremely limited.

As with previous mechanical soot blowers the use of the Diamond "VALV-IN-HEAD" effects a saving of four to eight per cent. fuel. As compared to previous mechanical soot blowers the Diamond "VALV-IN-HEAD" possesses the following distinct advantages:

1. **Labor for Operation**—A saving of approximately fifty per cent.
2. **Steam for Operation**—A saving of fifty to sixty per cent. or more.
3. **Pipe, Valves and Fittings**—A saving of fifty to sixty-six per cent. in cost of pipe, valves and fittings.

Remember that Diamond blower elements used in the hot passes of water tube boilers are CALORIZED.

One of the most interesting publications in the power plant field is the bulletin describing Diamond "VALV-IN-HEAD" soot blowers.

To secure your copy ask for Bulletin 287.

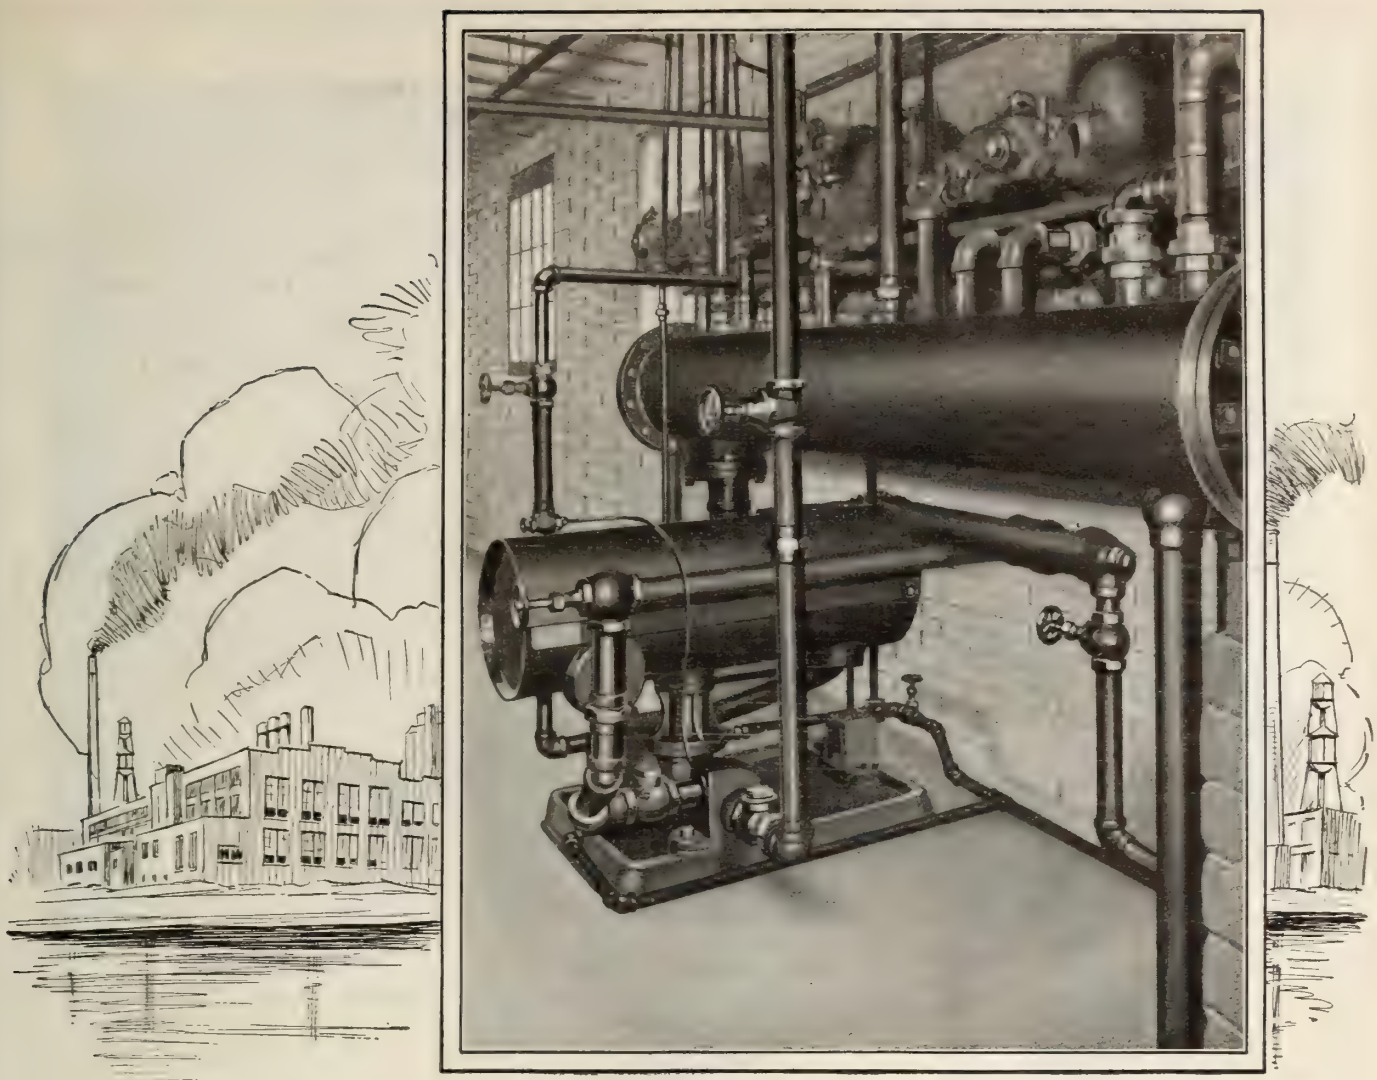
WINDSOR, ONT.

Diamond
VALV-IN-HEAD SOOT BLOWERS



Better Steam Drainage; Reduced Fuel Costs

Improved drainage of steam heated equipment and heating systems—better steam circulation—increased temperature of boiler feed water—reduced fuel consumption and the utilization of all condensation at its original high temperature—these are some of the results you may expect by the installation of a C. S. C. Steam Trap System in your plant.

By returning the condensation from steam lines at a temperature of 212 degrees or higher, direct to boilers, without the aid of pumps, C. S. C. Systems make possible a fuel saving of 15 per cent or more.

If you have a heating problem—a building difficult to heat because of inefficient circulation in steam lines—you are assured that the C. S. C. System will keep that heating system at topmost efficiency. Write today for our booklet in which the C. S. C. System is described in detail.

Method of Reading Steam Tables Correctly

An Explanation of What Each Column in the Steam Table Really Means, and Some Examples of the Method of Application to Every Day Problems

By T. H. FENNER, A.M.E.I.C.

THERE seems to be a doubt in the minds of many engineers when making calculations of the heat in steam, and water, of the proper method of handling the steam tables. We are driven to this conclusion by the result of questions put in the form of an examination to a number of candidates for the graded certificates, and it seems that perhaps a little explanation of this matter might be timely. It would seem at first glance as though there were but little chance of making any mistake, when the tables are so complete, but we have conclusive evidence that mistakes are made. It is our purpose then to examine the steam table in detail, and show how it should be used to obtain correct results in a number of different instances.

Properties of Steam

The particulars given in the steam tables are those of the properties of steam, that is the physical characteristics of the vapor formed when water is heated to certain temperatures. Leaving out the two last columns which deal with the entropy of water and of evaporation, which are quantities involving too much explanation to be treated here, the characteristics treated are eight in number. The table shown here is that of Marks and Davis, and is the accepted standard at the present date. Other tables are in use which differ slightly from this one, but the differences are chiefly in the latent heat at different pressures and temperatures, and are but slight. The table used by the Board of Examiners is somewhat older than this one, but as long as the work is done according to the table at hand the result will be correct for all practical purposes. In questions involving design, of course, the latest available table would be used.

First and governing all the other conditions, is the absolute pressure of the steam. This needs no explanation to the average engineer, it being the pressure measured from absolute vacuum, and is equal to gauge pressure plus 14.7 lbs.

The next column gives the temperature Fahrenheit of the steam at the pressure contained in the first column, and this temperature is, of course, measured from zero Fahrenheit. We will point out something in connection with this column a little later when we come to the column under the heading heat of liquid. The third column gives the volume in cubic feet of one pound of steam

at the pressure in the first column, and this is called the specific volume of the steam. This column and the column next to it are definitely related, the fourth column being the "Density" or weight of steam at the pressure in the first column. Now if one cubic foot of steam at 1 lb. per square inch absolute pressure occupies 333 cubic feet, then one cubic foot will weigh 1/333 pound. Now if we divide 333 into 1, we get

333) 1.000 (.003003
999
1000

which is given in the fourth column. We see then that the fourth column is the reciprocal of the third or the value of the third column divided into 1. Similarly if one cubic foot of steam at the pressure considered weighs .003 of a pound, then one pound of steam will occupy .003 divided into 1 or
.003) 1000 (333
and the third column is the reciprocal of the fourth.

The next column is the heat of the liquid. Now this heat of the liquid is the actual number of B. t. u. contained in the water at the temperature and pressure named, reckoned from 32 Fahrenheit. Here it must be observed that the column marked t, gives the temperature in degrees Fahrenheit measured from 32, while the column marked i, or heat of liquid, gives B. t. u. above 32. This is a point where many mistakes are made, because in considering the heat of the liquid many men merely take the temperature and subtract 32 from it. This will not give the correct result, except when the steam is in the neighborhood of atmospheric pressure, and the reason is this: the specific heat of water alters as its maximum density is departed from. Now take the example we have before us. The temperature of steam at one lb. absolute pressure is 101.83 degrees Fahrenheit. The heat of the liquid, or the heat contained in the water in contact with the steam is 69.8 B. t. u. above 32. The difference between 101.83 and 69.8 is 32.08, which is practically the same as 32. Turn now, however, to steam at a pressure of 49 lbs. absolute. The temperature is 279.8, while the heat of the liquid is 248.8. Subtracting 32 from the temperatures gives us 247.8, which is a difference of 1 B. t. u. from the heat given in the table. If we take steam at 150 lbs. absolute pressure we find that the temperature is 358.5, while the heat of the liquid is 330.2. Subtracting 32 from the temperature would only give 326.5, the difference being 3.7 B. t. u.

The alteration in the specific heat means that above and below 39.1 degrees Fahrenheit one pound of water requires less than one B. t. u. to raise it one degree Fahrenheit, and therefore there is more actual heat than is represented by the temperature.

If we divide the degrees above 32 in the temperature which will be 326.5 by the heat in the liquid, it will give us the specific heat of the water.

330.2) 326.5 (.9857
29718
28320
26416
19040
16510
25300
23114

Similarly if we divide the temperature above 32 by the specific heat we will get the heat of the liquid
9857) 3265000 (330.12

It will thus be seen that it is important to take the heat of the liquid rather than the temperature minus 32 degrees if accurate results are required.

We now come to the column which gives latent heat, and this is, of course, in B. t. u. This represents the quantity of heat that must be added to water at the temperature corresponding to the pressure, before it will become steam at the same temperature and pressure. This heat is called latent because it does not appear as an addition to the temperature of the steam, but is absorbed by the steam, and represents the larger part of the energy of the steam. Before steam can be condensed this latent heat must be carried away or given up, either to circulate water, or by performing work on which the heat is expended.

The total heat contained in the steam is given in the next column. This total heat is the sum of the latent heat and the heat in the liquid above 32, and represents the energy available in the steam to be turned into the work. The equivalent of one B. t. u. is 778 foot pounds of work, and therefore steam at 14.7 lbs. absolute, contains in each pound weight a total quantity of energy represented by 1150.4 x 778, which is 895.011.2 foot pounds. If we could extract all this energy in one minute it would represent 27.1 horse power, but unfortunately we cannot do anything of the kind. If we use the steam in an atmospheric exhaust engine we have to reject unused all the latent heat, besides losses by radiation in the engine and before it gets there. If we lose nothing but the latent heat rejected in the exhaust we would only get about 15 per cent. of the energy from the steam, but in actual practice we get considerably less than that. However, we do not want to go into that question just now.

Internal Energy of Steam

In the table under consideration there is a column which gives the internal energy of steam at the latent heat of evaporation. This internal heat energy requires a little explanation, but can readily be understood by a simple calculation.

Let us take a cylinder whose area is exactly one square foot and whose height is 26.79 feet. The volume of this cylinder would be 26.79 cubic feet, and this is the exact volume of one pound of steam at atmospheric pressure.

Let us suppose that one pound of water at 32 degrees Fahrenheit is lying in the cylinder, and that we apply heat to this water until it is all turned into steam. The pressure of the atmosphere may be represented by a frictionless piston, lying on the top of the water, whose weight is just equal to 14.7 x 144, this being the pressure of the atmosphere on the surface of the water.

The volume occupied by the water before heating will be 1/62.5. This is obtained from the fact that one cubic foot of water occupies 62.5 cubic feet, and therefore the volume of one pound of water will be 1/62.5 part of that. This works out to .016, which will represent the height of the surface of the water in the cylinder before heating is commenced.

We now apply heat to the water, and after we have added 180 degrees to it, the temperature reached 212, or boiling point. This addition of heat is sensible, inasmuch as it appears on the thermometer, and has been expended in raising temperature. After this point is reached, a further 970.4 B. t. u. must be added to make the water at 212 degrees into steam at 212. When this is done, the cylinder is filled with steam and the piston has been raised to the top. Let us see what this means in energy expended.

We have a total quantity of heat in the steam of 1150.4 B. t. u. The latent heat is 970.4. The height that the piston has been raised will be 26.79 less .016, or 26.774 feet. This is equivalent to raising a weight of 14.7 x 144 through a height of 26.774 feet and the energy expended in doing this is equal to

$$\frac{14.7 \times 144 \times 26.774}{778} \text{ B. t. u.}$$

This works out exactly 72.8 heat units, and this represents the external energy or the energy expended by the steam in overcoming the resistance of the atmosphere while expanding. The energy remaining in the steam will be 970.4 less 72.8 which is 897.6 B. t. u.

This is the explanation of the column "Internal Energy."

Using the Table

A typical example of the use of the steam table may be found in the formula for finding the saving by heating feed water. The saving effected is, of course, the difference between the heat added in the feed heater and the total heat added to the feed water to bring it to steam at the boiler pressure. This formula is given as follows:

$$\frac{T_2 - T_1}{S + L - T_1} \times 100$$

in which T_2 is the temperature of the water leaving heater, T_1 is the water entering the heater, S is the temperature of steam and L is the latent heat.

Suppose we have cold water at 40 deg. raised to 160 deg. in the heater, and steam is at 45 lbs. absolute.

We have

$$\frac{160 - 40}{274.5 + 928.2 - 40} \times 100$$

$$= \frac{120}{1162.7} \times 100$$

which gives 10.3 per cent saving. Now suppose we take instead of the first formula, a similar but not quite identical one.

$$\frac{(T_2 - 32) - (T_1 - 32)}{S + L - (T_1 - 32)} \times 100$$

In this case S is the total heat in steam instead of the temperature, and the other quantities are taken above 32 degrees instead of above zero.

We have

$$\frac{(160 - 32) - (40 - 32)}{243.4 + 928.2 - (40 - 32)} \times 100$$

$$= \frac{120 \times 100}{1163.6}$$

The result is practically the same. It will be noticed that the result of the top line is not affected by subtracting 32 from each term. It is only the bottom line that is affected, and only to the extent of the difference caused by the specific heat at the higher temperature.

This difference will be greater the higher the pressure of steam carried in the boiler.

Another example of the use of the table would be as follows:—What is the resulting temperature when 50 lbs. of steam at 125 lbs. pressure are mixed with 100 lbs. of water at 60 degrees, the mixture taking place at atmospheric pressure?

We see that the temperature of the steam at 125 lbs. is 355.1 degrees, while the latent heat is 867.6. The total heat above 32 is 1192.2 B. t. u. However, as the steam and water are to mix at atmospheric pressure, whatever steam is condensed will be condensed at atmospheric pressure, and its latent heat will be 970.4. Therefore we see that the steam must give up a certain quantity of heat in falling from 353.1 to 212 before any condensation will take place. Now if we consider the drop in temperature from 353.1 to 212 as purely a temperature drop the difference is 141.1, and this is the amount of heat given up by each pound of steam in falling from 125 lbs. to atmospheric pressure, and in condensing a further 970.4 B. t. u., will be given up so that each pound of steam in condensing will give up to the water 1111.3 B. t. u. Now if we take instead the quantity of heat above 32 in the steam at 125 lbs. we get 1192.2, and the total heat above 32 at atmospheric pressure is 1150.4 so that the heat given up in falling from 125 to atmospheric would be 41.8, and in condensing a further 970 4 would be given up. the total heat given up being 1111.8 B. t. u. The difference in the two methods is but slight, but it exists. As a matter of fact, in considering problems dealing with the temperature of a mixture, the first method dealing with the temperatures direct instead of considering the total heat above 32 are usually accurate enough.

In the problem stated here, we can say

Heat given up by steam in falling from 353.1 to 212 per lb. .. 141.1
Heat given up by steam in condensing 970.4 ..... 970.4

1111.5

Heat per lb. of water from 60 to 212 is 152 B. t. u. and as there are 100 lbs. of water, 15200 B. t. u. will be required to raise the water to 212. There are 50 lbs. of steam, and the total heat given up if it were all condensed would be 55575 B. t. u. Therefore after the water is raised to boiling point there would be 40375 B. t. u. still available, and if we divide this by 970.4 it will give us the number of pounds of steam not condensed. This comes to 41.6 lbs. steam not condensed, so that the mixture will consist of 108.4 lbs. water and 41.6 lbs. steam at atmospheric pressure.

We can reach this result in another way, by means of a simple equation. We know that the heat taken up by the water will be 100 (212 — 60), which is 15200. We also know that the heat given up by the steam in falling from 353.1 to 212, will be 50 x 141.1 which is 7055 B. t. u. This leaves 15200 — 7055, which is 8145 B. t. u. to be made up and this is exactly the heat given up by the condensation of 8.39 lbs. of steam at 212. This is found, of course, by dividing 8145 by 970.4.

In equation form this would appear as follows:

Heat gained by water = Heat lost by steam.

$$100\ (212 - 60) = 50\ (353.1 - 212) + x970$$

$$15200 = 7055 + x970$$

$$15200 - 7055 = x970$$

$$8145 = x970$$

$$x = \frac{8145}{970}$$

$$x = 8.39$$

This gives the same result as before, 108.39 lbs. of water, and 41.61 lbs. steam uncondensed. There is another method which can be used, as follows:

$$T = \frac{W_1 t_1 + W_2 t_2 + W_2 L}{W_1 + W_2}$$

Where T = final temperature
t_1 = temperature of water
t_2 = temperature of water
L = Latent heat
W_1 = Weight of water
W_2 = Weight of steam

$$T = \frac{100 \times 60 + 50 \times 353.1 + 50 \times 970.4}{100 + 50}$$

$$= \frac{6000 + 17655 + 48520}{150}$$

$$= \frac{71905}{150}$$

$$= 479.36$$

Now we cannot have a temperature of 479.36 at atmospheric pressure. Therefore find how much heat above 212 is contained in the mixture.

(479.36 — 212) 150 = 40104

If we divide this by 970.4 we shall have the quantity of steam not condensed

$$\frac{40104}{970.4} = 41.3 \text{ lbs.}$$

The above examples should give the reader an idea of how the steam table is to be used in all problems relating to the heat of steam, such as occur in questions of feed heaters and exhaust steam heating, quantity of water required for condensing, etc.

It does not pretend to cover the subject, but is merely meant as a guide for those who have had difficulty in finding the quantities required from the table.

SAMPLING DELIVERED COAL

In sampling delivered coal the Bureau of Mines follows a definite procedure. A sample weighing not less than 1,000 pounds is systematically collected by taking equal increments at regular intervals throughout the delivery, while coal is being loaded or unloaded, and crushing and reducing this sample by successive stages to laboratory size. In using analyses of samples of delivered coal, the reader must recognize that the coal is not always of uniform size, and that the impurities are not uniformly distributed throughout the mass. Some variations in the results obtained are consequently to be expected; if the same mass of coal were sampled a number of times the analyses would not agree absolutely except by chance. It is only when a considerable number of such analyses are available representing a considerable tonnage mined over a period of time that the average value and range of variation of a particular coal becomes known with assurance. With reasonable tolerances, however, for these variations, delivered coal can be sampled accurately enough for all practical purposes. Deliveries from any one mine may vary in quality from time to time because of changes in mining or preparing the coal, and an analysis of deliveries for any one date should not be considered as establishing a permanent standard, for the output may be greatly improved by new methods of mining and preparation, or it may deteriorate through the carelessness of the miner and the operator.

The St. Lawrence Co., Ltd., Montreal, who recently became agents for the Queen City Rubber Co., Philadelphia, not only cover Quebec but all of Canada east of and including Ottawa. They also have the right to sell other lines in any other part of Canada should they desire.

Some Elements of Economy in Air Compression

Steam Driven Air Compressors of Single and Compound Types —Electrically Driven Machines—Methods of Lubrication and Governing—Cooling by Water Jacket and Intercoolers—Types of Valves, etc.

By WM. CARTER, A.M., A.S.M.E.*
*Assistant General Sales Manager, Canadian Ingersoll Rand Co.

THE IDEAL inlet valve is here outlined. Probably no compressor valve on the market to-day exactly fulfils all these conditions; but many types represent the experienced judgment of the builders applied in an excellent compromise.

The functions of an air discharge valve are to release the full volume of compressed air from the cylinder with the least friction and power expenditure; to keep it all out after discharge, and to continue indefinitely to maintain this duty without undue expense. The primary essentials of such a valve are as follows:

Its opening must be full and instantaneous, must occur just at the right point in the stroke and must be held open until the piston comes to rest. The valve opening must be ample so that the velocity of discharge may not be excessive and the ports and discharge passages should be short and free from obstruction, to reduce friction.

As few parts as possible, and these correctly adjusted, should provide for the necessary valve movement with the minimum loss of power in mechanical friction.

The valve should close instantly and completely as soon as the piston stops, that there may be no return of the air discharged when the piston starts on its back stroke. Such a return of compressed air would have the effect of an increased clearance, reducing the capacity of the cylinder.

The continued maintenance of this performance (which is more arduous upon the discharge valves than upon the inlet valves because of the higher pressure) suggests the advisability of a simple construction with the fewest bearings, careful workmanship, the use of good materials, perfect lubrication and careful distribution of materials. It is always to be remembered that discharge valves and ports are continually exposed to a flow of heated air even where jacketing is most complete. On the other hand, an essential of inlet valves and ports is that they shall be kept cool. The latter should therefore be removed as far as possible from the former, nor should the same ports be used for both inlet and outlet.

It might, at first glance, seem that the area of the discharge valves, ports and passages could be much less than the corresponding inlet area, since the former must pass the air at a higher pressure and in less volume than the latter. But it is to be remembered that while the inlet areas are open during the full stroke, the discharge areas are open for only a part of the stroke—about one-third. In order, therefore, to make the velocity of discharge about the same as that of intake or admission, it is usual to make the inlet and discharge areas approximately equal.

It is important that the velocity of flow through the valves, ports and passages shall not be excessive, and this depends upon the piston speed which is a widely variable quantity. The higher the piston speed, the larger should be the area. In actual practice, the inlet areas vary from 3 to 15 per cent. of the cylinder areas, with an average probably around 9 to 10 per cent. The corresponding discharge areas from 7 to 15 per cent., with an average in the neighborhood of 10 to 12 per cent. The larger these areas, the better the economy. The modern design, the lightness of weight of plate and strip type of valves permit higher velocities than was formerly considered good practice. This is owing to the small differences in pressure required to open the valve and concentration of engineering talent in the correct shape and design in the ports through the air valve to give the least resistance to the air flow.

Owing to the increased friction through a number of small passages as compared with that through a single large one, the actual measured area in the former case should be 50 to 100 per cent. larger than the latter. This explains why the measured inlet area of machines with Corliss or other large area inlet valves is often so much less than the measured discharge area of many small poppet discharge valves, while still giving good results.

It may be well to recall at this point that cylinder clearance is really made up of three elements; the inlet port clearance, which is all the space left between the closed inlet valves and the inner surface of the cylinder, the discharge port clearance, which is the corresponding space in the discharge passage, and the piston clearance, which is the space allowed for safety between piston and cylinder head at the end of the stroke. This latter element is an essential in compressors. But it is not unusual for the other two elements together to constitute by far the larger proportion of the total clearance. This suggests the superiority of those valve designs in which inlet and discharge port clearance are reduced to the lowest practical limit.

Coming now to consideration of the third element in air compression, the mechanical structure, we find that it has a very important bearing upon the economy and the endurance of the machine.

The mechanical efficiency of a compressor can be exactly determined by a comparison of the steam and air indicator cards, (in a steam driven machine) or by a comparison of the measured power applied to the horsepower of the air indicator card (in a power driven machine). The difference between these values represents the power consumed in the friction of the compressor. Good mechanical efficiency, therefore, depends upon the extent to which friction is reduced. There is no time here to enter into the details of compressor design, it will be enough to enumerate some points having a bearing on this subject.

Power should be applied to resistance —steam pressure to air pressure—in as direct a manner as possible, so that bending or deflecting strains may be avoided as far as possible, with the resultant bindings of bearings and loss of correct alignment.

Ample metal should be used, properly disposed to afford the rigidity necessary as a further precaution against the attendant binding stresses, just mentioned. A light construction is always to be avoided.

Lest this correct proportioning of materials to meet stresses should result in an excessive weight and an extravagant cost, these materials should be of the best quality and intelligently selected for specific purposes, affording the maximum strength per unit of weight.

All bearings should be of ample area, so proportioned as to give a safe, moderate pressure per inch of bearing surface.

Wherever possible bearings should be supplied with removable linings (preferably of anti-friction metal). In all cases, whether thus lined or otherwise, they should be scraped smooth and true, properly adjusted and arranged for the ready distribution of lubricant—all of this tending toward a lower co-efficient of friction for these bearing surfaces.

Complete provision should be made for a plentiful supply of lubricant to all bearing surfaces, furnished preferably by an automatic system which will be efficient at all speeds.

The utmost simplicity should be sought throughout, reducing the number of parts, the number of joints, (each an

element of weakness) and the number of bearings with their attendant friction and their possible loss of economical adjustment.

The design should afford a ready accessibility at every point, inviting frequent and careful attention to the maintaining of a correct adjustment of all parts for most efficient operation.

Steam compounding and compound air compression have important effects upon the mechanical efficiency, which have already been discussed in the proper place.

Friction has been aptly defined as "that portion of the power consumed by a machine in wearing itself out." This definition throws on the question of compressor endurance a light in which the importance of a high mechanical efficiency appears in bold relief. True economy is a question not of momentary results but of results covering months and years of continuous service under all conditions; and a compressor in which the percentage of "wearing out power is least," promises not only the highest, but also the longest record of sustained economy and satisfactory service.

Governors

While the regulating devices or governors used on air compressors vary in detail among the different builders, all may be divided, as far as the principle of operation is concerned, into two classes.

The first class is that applied to compressors with plain or adustable cut-off valves of flat or piston type. It operates by throttling the steam supply as load diminishes. Devices in this class consist fundamentally of a valve in the steam pipe, which is opened or closed by action of a piston in a cylinder, this piston being actuated by air pressure from the receiver. The movement of this piston is opposed by weights on a lever or by a spring, and the spring tension or the weights may be adjusted so that the governor valve is full open at any desired normal air pressure. But when pressure exceeds this limit, the tension of weight is overcome, and the valve in the steam supply is closed in a degree corresponding with the amount of excess pressure. This slows down the machine and reduces the volume of air discharged until such time as the normal pressure is reached, when the weights or spring tension again open the governor valve, and full speed is restored.

The second class includes governors applied to machine with Corliss steam valves. The mechanism consists of a pressure cylinder and piston with opposing weight or springs as described in the preceding paragraph, but in this case the movement of the governor, instead of throttling the steam, changes the cut-off of the steam valves, reducing speed under partial load, and restoring it as load increases. The resistance per stroke being the same throughout, a very slight change of cut-off, hardly affecting the economy, produces all the speed change necessary.

Both of these classes of governors include also a speed-limiting device, the more common form being the familiar fly-ball arrangement, which throttles the steam supply or greatly shortens, the cut-off when speed exceeds a certain limit, as it might in case an air pipe should break or other accident occur.

There are occasional instances in which governors of one or other of the above classes are used in connection with an unloader on the air end, so arranged that, as the speed falls off, the load is partially taken from the air end. These are the specialties of individual builders, and as such cannot be elaborated upon here. The two general classes defined cover the general requirements of this paper.

Since the power driven compressor is almost always a constant speed machine, the methods of regulation and governing described for variable speed steam driven machines evidently cannot here be applied. Constant speed means constant piston displacement, and the problem of delivering a variable volume of air with constant piston displacement, becomes one of making a portion of that displacement non-effective in the compression and delivery of air. Only the fundamental principles of several methods of accomplishing this will here be discussed.

The first method is really one of unloading, rather than of regulating. A pressure controlled mechanism is arranged so that when pressure exceeds normal due to excess of delivered volume over demand, a communication is opened between the two sides of the compressing piston. Usually this is accomplished by opening and holding open one or several of the discharge valves at both ends of the cylinder, the air then simply sweeping back and forth from one side of the piston to the other through the open valves and the air discharge passage. When normal pressure is restored, the valves are automatically closed, and compression and delivery are resumed. Evidently this is practically a total unloading of the machine for a longer or shorter period—a sudden release from load and a sudden resumption of load. Moreover, the air which is swept back and forth by the piston in its travel is air under full pressure, so that when the discharge valves suddenly close, the piston at once encounters a full cylinder of air at maximum pressure. These facts limit regulators of this class to machines of comparatively small capacity.

Another method provides by means of a pressure operated device for the total closing of the compressor intake under reduced demand. This form of unloading consists of a double disc valve on the intake of the compressor which closes completely when the desired air pressure is reached and prevents any more air being drawn into the cylinder. Owing to its construction it is always wide open or entirely closed, the movement of the valve being complete and quick so that there is no wire drawing or throttling of the incoming air. The operating device or auxiliary valve controlling this form of unloader is governed by means of a needle valve or separate auxiliary operating valve either of which operate when the desired air pressure is reached for which these valves are set.

When compressors are operated unloaded for long periods without resuming their load, the addition of a cylinder relief valve can be applied to keep down excessive temperatures. When these relief valves are applied they are operated simultaneously with the closing of the intake unloader. Their use permits entirely unloading the air cylinder by opening each end to the atmosphere. The use of cylinder relief valves is more particularly beneficial on straight line compression and where the ratios of compression are high.

A further modification of the use of the intake unloader has been developed by one of the large builders using the intake unloader in combination with a discharge line unloader for two-stage compression. The discharge line unloader is never used alone but only in connection with the intake unloader when it is desired to attain the greatest possible reduction in horsepower during unloading periods. It is connected directly to the discharge opening on the high pressure cylinder in such a manner that the flow of air through the device to the cylinder is to the atmosphere. The operation is instantaneous, opening a passage directly from the high pressure cylinder discharge passage to the atmosphere when unloaded. This is accomplished by opening a pressure operated valve which is controlled by the same auxiliary valve as controls the intake unloader. When the pressure operated valve is opened communication between the discharge passage from the high pressure cylinder is direct to the atmosphere and the air in the pipe line and receiver are held back by an automatic closing check valve. On the resumption of demand, the intake unloader opens and simultaneously the pressure operated valve in the discharge line unloader closes and the air is passed on to the receiver.

The third method is very similar to the first except that here the inlet valves instead of the discharge valves are held open when the machine is unloaded and in single stage machines the piston simply draws in and forces the air out to atmosphere. In the case of two-stage compression some or all of the inlet valves at each end of both the high and low pressure cylinders are held open. In the case of the low pressure cylinder the air is exhausted through the suction passage back of the atmosphere and the cool clean air is sent back and forth into the low pressure cylinder after the first air is exhausted. In the case of the high pressure cylinder the air is exhausted back into the intercooler and the piston sweeps back and forth in a balanced condition. This system of regulation can be applied in two steps on two-stage compressors so that half of the low pressure cylinder and half of the high pressure cylinder can be cut out at

a given pressure and the second half of the low pressure cylinder and the second half of the high pressure cylinder can be cut out at a slightly increased pressure. This form of regulating gives a regulation on the basis of "no load," 50 per cent. load and "full load." In this system of regulating, when the pressure drops to a predetermined point the valves are automatically closed and compression of delivery resumed. This form of regulating and unloading is applicable to single stage compressors and to two-stage compressors. It is also possible to use this form of regulation on steam driven compressors of the straight line type in combination with combined speed and pressure governors, where separate controlling or operating valve is used, which first acts on the steam governor slowing the machine down to a pre-determined number of revolutions per minute, after which the free air unloader will come into action and fully unload the machine. In the loading condition the free air unloader is first closed with a further drop of pressure the governor brings the compressor up to its rated speed.

The most superior method of regulation known to compressed air engineers and usually employed on two-stage compressors above 1,000 cu. ft., provides auxiliary clearance spaces or pockets at each end of the cylinder which successively cut in as the load diminishes. The excess air is simply compressed into these clearance spaces and expanded on the back stroke. The capacity of the cylinder is reduced without any appreciable waste of power, for the energy used in compressing the clearance air is given back by its own expansion. A big advantage of this type of unloading is that it is the only known method of unloading a two-stage compressor of two cylinders in four definite steps and still maintain both sides of the machine in balance. This is a particularly desirable feature on larger compressors where it is usual to employ direct connected synchronous motors. It might be said that a four step definite unloading can be accomplished with the free air unloader by using two low pressure and two high pressure cylinders.

In the clearance control method of unloading the practice is to have two clearance pocket control valves at each end of each cylinder which are controlled by an auxiliary valve. The accomplishment of four step unloading is caused by the auxiliary valve first opening up one valve at one end of the low pressure cylinder together with one valve on one high pressure cylinder at the same moment. This gives three-quarter capacity. A slight increase in the air pressure causes the auxiliary valve to open up one clearance control pocket in the opposite end of the low pressure cylinder together with reciprocal pockets at the opposite end of the high pressure cylinder.

A further increase in pressure operates the third stage bringing the load down to a quarter by means of opening up a second clearance valve on the low and high pressure cylinders on the same end on which the first stage was accomplished. A still further increase puts the compressor into fully unloaded condition by opening up the last clearance pockets which are located on the same end that accomplished the second stage or half load condition. As the demand for air increases the load comes on in steps in the reverse order.

In the odd cases where it is found advantageous to operate the compressor by means of automatic start and stop control electrical devices, special means must be taken to insure the compressor is unloaded when starting up from a position of rest with pressure in the air receiver. There are several methods of accomplishing this, and we shall only attempt to describe two or three of these.

One is by means of an electrical solenoid operating valve. This is somewhat of an expensive apparatus. Compressed air engineers have developed an entirely mechanical method which is cheaper than the solenoid method, which is operated by means of pilot valves attached to the indicator openings which operate a specially designed discharge line unloader. These operating valves are controlled by a peculiar air action in the cylinder at the moment the machine comes to rest and do not permit the discharge line unloader to allow the air to be pumped into the receiver until the compressor is up to speed.

On small vertical compressors which are very frequently used with automatic start and stop control a very simple device has been designed which operates by means of centrifugal action. The weights of the centrifugal unloader are attached to the end of the crank shaft and when the compressor comes to rest these weights control the operating rod which holds the inlet valve open. When the compressor is up to speed the inlet valve resumes its usual function.

On power driven compressors with Corliss intake valves, several different methods of unloading or regulating are used.

By one method the Corliss valve is held open for the full admission stroke, and also a part of the compression stroke, this latter portion being determined by the unloading called for. Evidently this is practically equivalent to a shortening of the stroke of the compressor.

By another method the Corliss intake valve is opened full at beginning of admission, but closes later in the admission stroke. The air admitted to that point is expanded or rarefied for the remainder of the compression stroke, and then compressed, the volume of compressed air delivered being of course reduced. This arrangement is productive of an excessive temperature range in the cylinder. Still a third method opens and holds open the intake valves at the end of the cylinder, or at opposite ends in duplex machines. The effect of this is to make ineffective one out of every two strokes. If still further unloading is necessary, the intake valves at the other end of the cylinders or cylinder are opened and held open. The three arrangements just outlined all operate by a pressure controlled mechanism which actuates some form of trip on the Corliss air valve gear, somewhat similar to the release mechanism of the Corliss steam valve for varying the cut-off.

Things to be Avoided

Three things are to be avoided in the successful unloader or regulator for power driven machines, first, a sudden release or resumption of load, throwing heavy strains on the machine; second, undue rarification of the intake air, resulting in a wide range of cylinder pressures and temperatures, third, the blowing off of compressed air to the atmosphere with a waste of power.

In the regulation of the power driven compressor, less reliance must be placed upon the automatic regulation of the individual machine than upon the intelligent subdivision of the load between two or more machines and upon the careful management of the resulting plant. In designing a plant of these machines, maximum capacity must be cared for in the normal output of the machine while partial loads are provided for by starting or stopping one or more machines, the remainder running at or very near full load. It is usually desirable to start a power driven compressor with no load, throwing on the load gradually after normal speed has been reached. This is, in fact, essential in machines driven by electric motors, for the heavy inrush of current in starting under load is dangerous, particularly where power is taken from a transmission circuit supplying other motors.

Evidently almost any of the unloading devices noted in the previous section can be used for this purpose if properly arranged for manipulation. The usual form, however, is simply a by-pass valve to atmosphere on the line close to the compressor protected by a check valve between it and the receiver to prevent the return of air from the line when the starting unloader valve is open. This check valve is essential where several compressors serve one line, permitting cutting in or out any machine without unloading the others. This by-pass valve is open on starting, when the compressor simply compresses to a pressure sufficient to open its discharge valves, this air escaping to atmosphere. When normal speed is reached, the by-pass or unloading valve is gradually closed and load resumed. On two stage machines, an unloader valve should be provided on the low pressure discharge of the intercooler, as well as on the high pressure discharge to the line. In the latter case, both cylinders operate momentarily as low pressure cylinders.

Horse Power of Gas Engines and Motors

The Method of Determining Brake Horse Power on Those Types of Engines Which Cannot Readily be Indicated, and on Electric Motors by the Dynamometer or "Prony" Brake

SMALL and medium sizes of gas engines and motors naturally call for a simple, cheap, and at the same time accurate method of ascertaining the horse-power developed and delivered to the lineshafting. This will consist of some form of dynamometer, which is generally the friction brake. Whether an engineer is likely to be called upon to make a test of this kind or not, it is a good plan to know how to do it, because of the satisfaction of knowing that should occasion require it he will be prepared to undertake the work

The simplest forms of brake and the cheapest constructions only will be illustrated, since they are not only more readily comprehended in a short time, but where an expensive outfit is required the owner of the engine, and sometimes the engineer also, prefer to take the builders' statement concerning the power and the economy to be obtained, instead of going to the expense of obtaining the necessary apparatus for a test.

One of the simplest and the cheapest forms of brake is the rope or differential brake, shown in Fig. 1. The pulley employed with this brake preferably has raised edges or flanges on the rim to prevent the rope from slipping off sidewise. Grooved pulleys are, of course, more perfectly adapted to the use of the rope brake, but it is applied with good results to the ordinary form of pulley face. If a flanged pulley is not conveniently obtained, the rope may be run through blocks of wood, the blocks having depending edges forming short sections of flanges, which prevent the rope moving sidewise. The method of increasing the tension on a rope will no doubt be determined by circumstances. A familiar method of doing this is shown in Fig. 1. One end of the double rope is hooked on to the lower end of a pair of spring scales, and the scales suspended from the short arm of a lever of convenient length, which is fulcrumed upon a bracket from the ceiling above or upon a trestle constructed expressly for it. The opposite end of the double rope is hooked on to the end of a lever fulcrumed at the middle, so that it is approximately balanced. The end opposite the brake rests upon the platform scales, as shown.

After starting the engine and getting the proper speed, the free end of the upper lever is gradually pulled down, which wraps the rope tightly around the pulley, and the friction tends to carry the rope around with the pulley, which tendency is overcome by the lever below. The stress created in the rope by the tendency of the latter to revolve with the pulley is measured by the platform scales, the scales being constantly adjusted so that the beam is kept in equilibrium or balance.

The indications of both scales are noted frequently, when the scale beam is exactly balanced and a record kept throughout the run. The power may be figured shortly after starting the engine, and if it is not high enough the lever may be pulled down a little farther, and the power again computed, and so on until the maximum power desired is reached. It is desirable to proceed in this manner when the volume of gas consumed per horse-power is to be obtained for several different loads. When only the maximum power is desired the rope can be tightened nearly to the proper point by noting the position or the action, as the case may be, of the governor. Then, when it is thought the full load has been obtained, the horse-power may be quickly computed and the amount of gas used from this moment on kept account of.

When finding the horse-power of the engine by means of the differential brake, the difference between the readings of the two scales is taken, and this represents the stress on the rope. The horse-power is found by the formula:—

$$\frac{D \times 3.1416 \times R \times S}{33{,}000} = \text{H. P.};$$

in which D = the diameter of the brake pulley, R = the revolutions per minute; and S = the stress on the rope previously mentioned. It is important that the calculation of the horse-power be performed as quickly as possible when increasing it from zero to the maximum, because the rope cannot be used continuously for long runs. To aid in doing this it is a good plan first to find the horse-power constant of the particular engine being tested. This is represented by the formula:—

$$\frac{D \times 3.1416 \times R}{33{,}000} = \text{H. P. constant.}$$

All that is necessary now when computing the horse-power is to find the difference between the readings of the scales, or the value of S, and multiply it by the constant, which can be done in about one-fourth the time necessary to use the entire formula.

When keeping account of the maximum values only, throughout the run, the average of these values will be used which is represented by the sum of the readings of the platform scales minus the sum of the readings of the spring scales and the difference divided by the product of the number of readings taken multiplied by the number of minutes. This rule in the form of a formula is:—

$$\frac{R - r}{M \times N} \cdot \text{average value of S.}$$

In this case R = readings of platform scales, and r = readings of the spring scales; M = number of minutes, and N = number of readings. The differential rope brake is applicable to engines of from 1 to 5 or 6 H. P., and may be rigged up in a short time with materials generally to be found in manufacturing plants.

Another simple form of brake is shown in Fig. 2. This, in principle, is the same as the rope brake, the calculations being the same. In the latter brake a strap is used instead of the rope, which may be a piece of leather belting reinforced at the ends for the reception of the hooks.

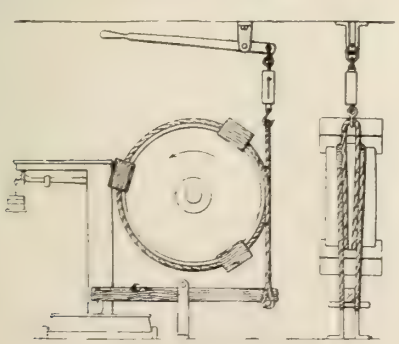

Fig. 1.

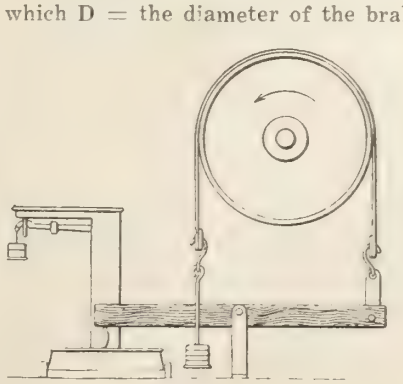

Fig. 2.

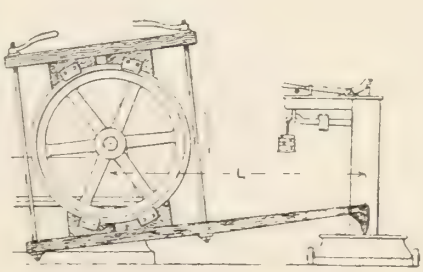

Fig. 3.

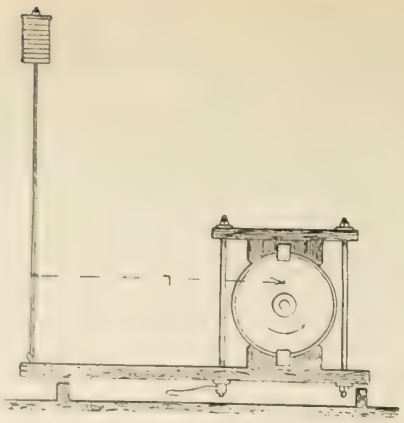
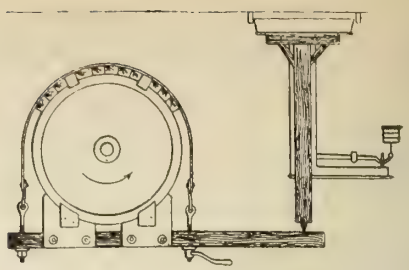
Blocks of wood may be fitted over the belt in practically the same manner as in the case of the rope brake to keep the belt from slipping off the pulley. For larger engines, say from 5 or 6 H. P. upward, the Prony brake illustrated in Fig. 3 is the better construction. While the brake is fully as simple when once constructed, it is, of course, a trifle more expensive, and will require a little longer time to rig it up. It consists of two or more blocks of wood bolted to suitable strips for the purpose of keeping them in position. The lever employed for weighing the resistance generally serves as one of these strips as shown. Ears are bolted on at the top and bottom, and project toward the hub of the wheel or pulley and about an inch beyond the rim of the pulley. These prevent the blocks from slipping off the pulley. Two heavy bolts run through the projecting ends of the upper cross-piece and also through the lever, with washers and nuts at the lower ends. The upper ends are provided with washers and lever nuts, or wingnuts as they are sometimes called. The outer end of the lever rests upon the scales, which are adjusted to balance the weight of the lever and the vertical bar supporting it.

After starting the engine and obtaining the desired speed, the lever nuts are tightened by hand until the desired resistance is obtained, or nearly so, the weights on the scale beam at the same time being put on so that as soon as the desired load has been obtained the scales may be quickly balanced and the weight indicated by them recorded. When the scales get out of balance, due to wear at the blocks, the latter must be tightened a very little so as to restore the balance of the scale beam without having to readjust the weights on the beam. It generally requires but a slight turning of the lever nuts to bring the scales into balance again, and it is usually impracticable to turn these nuts so slight an amount by hand. A less force than is necessary to move the nuts will frequently be sufficient to bring the scale beam into equilibrium, so that as soon as the nut is released the scales are immediately out of balance again. A light hammer is preferable when making these adjustments, giving the lever of the nut a slight tap, which will generally be found sufficient to move the nut without disturbing the scales other than by the increased resistance due to tightening the blocks on the pulley.

The brake blocks may be lubricated by water thrown upon the pulley surface by means of an ordinary squirt can, or the blocks may have grooves cut in the faces, of practically the same form as in the brasses of an engine connecting rod. The lubricant in this case may be a heavy grease which fills the grooves and is evenly distributed by them.

The calculation necessary with this form of brake differs but little from the calculation previously given. In the first place, the length of the lever L,





Figs. 3 and 5, is measured between the centre of the shaft and a vertical line passing through the point of support on the scales. The formula for horse-power is:—

$$\frac{D \times 3.1416 \times R \times (L \div r) \times W}{33{,}000} = \text{H. P.};$$

in which D = the diameter of the pulley; R = the number of revolutions per minute; L = the length of the lever resting upon the scales; r = the radius of the pulley; and W = the weight indicated by the scales. Another formula in common use is:—

$$\frac{2 \times L \times 3.1416 \times R \times W}{33{,}000} = \text{H. P.},$$

the notation being the same.

As in the former case, it saves time and is much more convenient to use the horse-power constant instead of employing the entire formula each time the power is obtained during the run. The horse-power constant in this case is obtained by the formula previously given, except that the value of W or the weight indicated by the scales is unknown beforehand, and therefore is omitted from the formula. The result of the formula will then give the horse-power for each pound indicated by the scales, so that when finding the horse-power at each adjustment of the brake it is only necessary to multiply the constant by the weight indicated by the scales; the result will be the horse-power delivered at that moment or while the scale beam is in equilibrium.

Still another form of brake suitable for engines of medium size is shown in Fig. 4. This is called the Prony strap brake. It consists of the lever and two blocks at the top, and a strap partly surrounds the pulley, having a number of smaller blocks attached to it on the underside of the pulley. Two or more ears are attached to the strap or to the blocks to prevent the latter from working off the pulley. The strap is fixed at one end and connected to an adjustable bolt at the other, the bolt extending through the lever, and is provided with a washer and lever nut. This brake is lubricated in the same manner as the others by means of water applied with a squirt can or a heavy grease. The blocks should be grooved when the latter is employed. The method of adjusting the screws and the necessary calculation are the same as with the two-block or four-block brake.

Some persons prefer to measure the power delivered from the lineshaft, instead of from the engine. When this is required the arrangement of brake illustrated in Fig. 5 is frequently found convenient. The brake may be either the block or strap construction. The lever lies at right angles to the direction of the weight cord when the weight is raised from the floor and the lever is in equilibrium. The lower disc or weight may be heavy enough to hold the lever in the position shown when the friction blocks are sliding loosely on the pulley. The effect is practically the same as when balancing the horizontal lever on the scales when the brake is running loosely on the pulley. The weights added at the bottom are the ones used in the calculation. These should be added as fast as the brake screws are tightened, so as to keep the weight suspended or just off the floor. The calculation of the horse-power with this arrangement is the same as with the brakes illustrated in Figs. 3 and 4.

These styles and constructions of brake represent the principal forms which can readily be made by the engineer or carpenter in almost any plant, and when carefully handled give results approximating the results obtained with more elaborate and costly apparatus. The whole brake should be made strong, yet as light as possible, and for this purpose poplar is a fairly good wood to use for the blocks, which are the heavier parts of the brake.

The friction brake or dynamometer does not furnish a means of finding the total horse-power developed by a gas engine, but the horse-power obtained from it. In order to find the horse-power developed by the engine itself, or the indicated horse-power, as it is called, it would be necessary to use the indicator. The application of the indicator to the steam engine is familiar to all. The application to the gas engine is made in much the same manner. Sometimes the indicator port is located in the clearance space, the instrument then being placed

either on top or at the side of the cylinder, while in other engines the port is in the cylinder head. The drum cord is attached to any convenient part of the engine that moves in unison with the piston so as to impart to the drum an exact reproduction of the piston movement.

It is not intended to go into the work of taking diagrams and finding the mean effective pressure, because that should properly be treated in a separate article. In connection with the formulae for finding the horse-power constant used when applying the brake, those to be used when applying the indicator may be added. For the two-cycle engine, in which the speed is governed by throttling the supply of gas, the formula for horse-power is:—

$$\frac{P \times L \times A \times N}{33{,}000} = \text{H. P.}$$

In the four-cycle engine governed in a similar manner the formula is:—

$$\frac{P \times L \times A \times \frac{1}{2} N N}{33{,}000} = \text{H. P.}$$

For the four-cycle engine operating on the hit-and-miss principle the formula is:—

$$\frac{P \times L \times A \times E}{33{,}000} = \text{H. P.}$$

In the case of the former engines the value of P or the mean effective pressure will under ordinary circumstances be the unknown quantity, and the formula for the horse-power constant becomes:—

$$\frac{L \times A \times N}{33{,}000} = \text{H. P. for 1 lb. mean effective pressure.}$$

In engines operating on the hit-and-miss plan there are two unknown quantities—viz., the mean effective pressure and the number of explosions per minute. The constant in this case is:—

$$\frac{L \times A}{33{,}000} = \text{H. P. for 1 lb. mean effective pressure and for one explosion per minute.}$$

It will be understood that this refers to the average mean effective pressure from the several diagrams taken.

The letters in the foregoing formulae represent the following quantities: A = area of piston in square inches; L = length of stroke in feet; N = number of revolutions per minute; P = effective pressure in pounds per square inch; and E = the number of explosions occurring per minute.—"Southern Engineer."

HEATING BOILER FUELS

Technical Paper 303, "Value of coke, anthracite, and bituminous coal for generating steam in a low-pressure cast-iron boiler," by John Blizard, James Neil, and F. C. Houghton, has just been issued by the Bureau of Mines.

The primary purpose of the tests described in this paper was to determine the relative steaming values of coke, anthracite, and bituminous coal when burned in a low-pressure boiler, and fired by hand in fairly large quantities at a time.

A secondary purpose of the tests was to separate the heat losses, and to examine them carefully to determine the change in efficiency with the method of firing the fuel and manipulation of the draft dampers, with the rate of evaporation, and with the various fuels burned.

Other purposes were the determination of the draft used, temperatures and composition of the gases in the flues, furnace, and combustion chamber, and other factors affecting the operation of the boiler.

Before these tests were completed, some special tests were run at the request of the Chamber of Commerce of Pittsburgh, to compare the steaming value and smoke emission of mixtures of coke breeze and Pittsburgh coal with those of the latter alone; results of these tests are also embodied in this report.

Tests were made at different rates of steaming with coke, anthracite, and bituminous coal. Two tests also were run with a mixture of equal weights of bituminous coal and fairly coarse coke breeze, and two more with a mixture of equal weights of bituminous coal and a finer coke breeze. The calorific value of the coke ranged from 10,700 to 11,900 B. t. u. per pound; of the anthracite from 11,700 to 13 300 B. t. u.; of the bituminous coal from 12,900 to 13,900 B. t. u.; and of the coke breeze-bituminous coal mixture from 11,200 to 11,800 B. t. u. The bituminous coal contained less ash than the coke or anthracite, about the same proportion of moisture, and, of course, far more volatile matter.

The mean steaming values of the coke, anthracite, and bituminous coals were about the same. At the low rate of steaming the coke and anthracite evaporated more water than the bituminous coal, and at the higher rates of steaming the bituminous coal evaporated more water than the coke or the anthracite. The steaming value of the mixture of coarser coke breeze and bituminous coal was about 80 per cent. of that of bituminous coal alone, whereas the mean steaming value of the mixture of finer coke breeze and bituminous coal was lower than that of the mixture of coarser coke breeze.

Technical Paper 303 may be obtained from the Bureau of Mines, Washington, D. C.

DO YOU BUY YOUR OWN BELT DRESSING?

(Copyright, 1922, By W. F. Schaphorst)

A writer in a prominent technical publication recently stated that. "in the old days mechanics were in the habit of making their own glues, cements, belt dressings, etc." However, he went on and said that times have changed and that as a result to-day a great many of our mechanics do not do any mixing at all but buy factory-made preparations.

Then the writer continues and, according to my viewpoint, he inconsistently says:

"Personally I make nothing but belt dressings. For leather belting I use, by weight, two parts of beef tallow and one part cod liver oil. First melt the tallow and allow it to cool until it is little better than lukewarm, then the cod liver oil is thoroughly stirred into it."

He also gives a recipe for rubber belts, which involves red lead, black lead, French yellow and litharge, not to mention boiled linseed oil and japan, etc.

In view of the ingredients used by the above mechanic, the writer is convinced that it would be much better if he would refrain from mixing his own belt dressings also, and purchase a good reliable dressing such as he will find advertised in our trade publications. These dressings do not contain substances that have proven to be actually harmful to belts, such as tallow, boiled linseed oil, litharge, etc.

There are concerns in the United States who have spent a great deal of time and money in the development of belt dressings for all kinds of belts and it is but natural that they should know more about belt dressings than a person who has not made the subject his life study. These manufacturers produce dressings in large quantities, dressings that do not contain the harmful substances, but rather substances that are preservative and that benefit the belt instead of harming it.

The writer does not manufacture dresssings, but has had considerable experience with dressings, both "home made" and factory made and he has come to the conclusion that it pays in the end to buy the best dressing on the market instead of bothering with questionable substitutes. Years ago I did a little house and barn painting and I mixed my own paints, believing that I mixed better paint than could be bought. However, I have since found that I was badly mistaken. To-day the painter who insists upon mixing his own paint, who says that he can mix paints better than can be done by machinery, can safely be put down as an "old fogey."

FIRE HAZARDS IN OIL REFINERIES

Fires in oil refineries may be caused by lightning or other mishap, or by carelessness in allowing the oil or vapors to become ignited, states the U. S. Bureau of Mines in Serial 2,400, just issued. Probably the most frequent cause, however, is the failure of refining equipment. Stills are designed to be safe; and usually are safe. Nevertheless, defects sometimes occur, as in all metal structures, and unless promptly discovered and remedied may result in serious fires and explosions. The dangers of refining crude oil are well recognized, and all modern refineries have developed highly efficient systems of inspection and fire prevention.

Tension and Working Strains of Belt Fasteners

Value as a Transmitting Medium—Only Fraction of Actual Strength of Belt Needed for Delivering Power—Various Grades of Belts Considered—Maximum Load on Fastener

By ERNEST D. WILSON, B.Sc., Ph.D.

THE VALUE of belting for transmission work is determined by its gravity and its horse power transmitting qualities rather than by its tensile strength. If this were not so, it would be comparatively simple for a belting manufacturer to combine certain materials and produce a belt with a tensile strength far beyond any at the present time on the market, but such a belt might have little or no value as a power transmitting medium. It is very interesting to note that in no case, in a very large series of tests conducted by the Mellon Institute and at Cornell University on power factors with the power transmission of belts, has a tension of over 1,000 pounds per square inch been obtained, even under loads several hundred per cent. larger than the rated capacity of the belts. Since the tensile strength of most belting materials is almost invariably more than 3,000 pounds per square inch, it is evident that only a fraction of the actual strength of the belt is needed for transmitting power.

The same thing applies to belt lacing. If strength alone were desired, a fastener could easily be designed which would never let go, but it would have little or no value as a practical belt lacing. Belt lacing should be sufficiently strong to carry maximum loads with a reasonable amount of safety. It should be durable, flexible, smooth on both sides, and should not injure or weaken the ends of the belting. Even though the use of belts to transmit power is very common, few people have a clear conception of just how and why they do transmit power. In studying the strength required of belt fasteners, it is necessary to clearly understand the mechanism and the stresses involved.

Author is consulting engineer of Clipper Belt Lacer Co., formerly of the Mellon Institute, and Chief Engineer Graton and Knight Mfg. Co.

Effective Tension

Consider a belt placed over a pulley and drawn tightly against the pulley surface. If one strand of the belt is pulled harder than the other, either the pulley turns or the belt slips over the pulley surface. The sum of the tensions on both strands of the belt measures the force with which the belt is held against the pulley face and also the friction load on the bearing. The difference in the tensions of the two strands measures the turning force applied to the pulley, and is often called the "effective tension."

As the belt is turning and transmitting power it is easy to see that the highest tension in the belt is the tension of the tight strand and any fastener must be capable of withstanding this tension, with a fair margin of safety to spare. The question then becomes, "What tensions may we expect in a belt carrying its normal load?"

Ratio of Tension Between T. & L. Strands	Effective Tension or Pulling Strain	Tension in Tight Strand	Tension in Loose Strand	Total Tension causing Bearing Friction
6 to 1	60	72	12	84
5 to 1	60	75	15	90
4 to 1	60	80	20	100
3 to 1	60	90	30	120
2 to 1	60	120	60	180

Surface of Belt

The poorer the surface of the belt, the lower is its power-transmitting capacity, and the higher the tension must be to transmit a given amount of power. Belts with good surfaces run constantly with the slack strand actually sagging and show a tension of from ten to twenty times as high in the tight strand as in the loose, whereas when a belt will only allow two times the tension in the tight side as in the loose (which unfortunately is sometimes the case) it is a very poor belt indeed, and has an extremely poor surface.

In the following table the tensions developed with belts of various grades are considered. In each case the belts were run under an effective tension of 60 pounds per inch of width, which is about the maximum recommended by the manufacturers for single leather or four-ply canvas or rubber belt.

In the table given each line shows the tensions which would exist in belts of varying quality as to surface, all 1 inch wide traveling at the same speed, and transmitting the same amount of power. In the second case shown where the tension in the tight strand is 75 pounds, the slack strand carries 15 pounds, and the belt forces the shaft against its bearing with a force of 90 pounds. Contrast this with the extreme case of ratio of two to one. The tight side of the belt must withstand 120 pounds pull and the

INTRODUCTORY

W. B. ROBERTS

W. B. ROBERTS, successor to Thos. H. Fenner, whose valedictory as editor of Power House appeared in the issue of November 20, comes exceedingly well qualified to assume the duties and responsibilities of the position. To readers of this paper it will be of particular interest to know that Mr. Roberts has had practical experience of an exceptional character as stationary engineer. He holds an Extra Chief Engineer's Board of Trade certificate. In 1908 he became associated with the Manchester Steam Users' Association of Manchester, England, first as surveyor and latterly as resident and consultant to the Association. He was with them for five years, when he was in the unique and favorable position of observing numerous tests conducted with a view to promoting economy in the application of steam. Mr. Roberts' subsequent experiences have brought him into close touch with Canadian activities and with the problems confronting Canadian stationary engineers relative to the operation of steam power plants.

In his late capacity as chief engineer and manager to the Boiler and Engine Department of the General Accident Assurance Company of Canada, Mr. Roberts was frequently in consultation with important clients such as pulp and paper companies, manufacturers in many other lines, power stations, etc. Thus, he was called upon for advice in various matters appertaining to engineering, and became familiar with power problems and their solutions in Canada.

It was during the war that Mr. Roberts added a most interesting chapter to his career. In 1915, he was inspector for Alberta and Saskatchewan in the service of the General Accident Assurance Co. He left this position temporarily to join His Majesty's Navy. The manager of the company on that occasion wrote: "It is with great regret that we permit him to leave temporarily, but his country calls him. He is very highly qualified as an engineer, holding an Extra Chief's Certificate, and he wishes to obtain a position in the navy where his service can be used for the good of the Empire." Subsequently, Mr. Roberts served in H. M. minesweepers as Engineer-Lieutenant from February, 1916, and as Engineer Lieutenant-Commander from March, 1919, until demobilization in June, 1919. For a period of twelve months he was employed in the Clyde District supervising the construction of new vessels. There was a programme of twelve H. M. vessels and the shipbuilding yards were very widely spread out, extending on the East coast from Dundee to Hull. This programme was successfully carried through from laying the keel-plate, conducting all the necessary tests and eventually running the final trials. Engineer Commander Chas. J. M. Wallace writes: "He displayed great tact in dealing with the various engineering firms concerned and so expedited the completion of these ships when they were urgently required. Mr. Roberts has shown himself to be a clever and capable engineer and a good organizer."

During the period of his sea service he was chief engineer on six H. M. vessels. The reason for this was that he was unfortunately regarded as "trouble-man" and therefore was being constantly changed about on the various vessels where trouble was thickest. This was during the period of the war when our merchant shipping losses were heaviest and therefore every H. M. vessel that could be possibly kept in commission was kept at work.

On the completion of his work in the Clyde District, Mr. Roberts was appointed to the Portsmouth Base in charge of repairs. Some of his experiences here were unique in view of the fact that he was effecting repairs under great difficulties during the steel shortage. His rank here was Engineer Lieutenant-Commander.

Mr. Roberts is thoroughly conversant with the installation of power plants, consistent with the best modern practice. He has an Extra Chief Engineer's Board of Trade Certificate, which examination is equivalent to the Canadian B. Sc. degree in engineering. He has had wide experience as a draughtsman, and is well up in the theory of engineering.

It is a pleasure to introduce such a one as Mr. Roberts to the readers of Power House. His training and experience, engender the confidence that he is well equipped to appreciate the problems and ambitions of the Canadian field. His wishes are that he be always considered available for consultation, that he welcomes suggestion and helpful criticism, and that, in a spirit of whole-hearted co-operation, he hopes for a full measure of success.

Progress in New Equipment

THE HAUCK Venturi Fuel Oil Burner, see Fig. 1, is a new and improved type of atomizer in which oil is completely atomized or broken up into finely divided fog-like particles by means of steam or compressed air.

The burner consists essentially of a cylindrical casing with slots parallel to the bore axis. These slots form with the inner wall of the casing longitudinal ports or orifices through which the atomized oil is impelled into the furnace. Each port or orifice is a small Venturi tube constricted at its center and flared outwardly at the two ends. The throats or constricted parts of the orifices are connected with the interior of the bore by means of radial openings or apertures.

The oil or tar is delivered under a pressure of 40 to 60 lbs. per sq. in. to the bore, and then passed through the radial apertures to the orifices where it is collided against and blasted by the compressed air or steam.

The compressed air or steam is delivered to the burner at about 80 to 100 lbs. per sq. in. pressure. As it flows through the ports, its velocity increases rapidly and becomes a maximum at the orifice throats. Here it strikes and blasts the oil, atomizes it thoroughly, even by-product tar, and impels the atomized oil from the burner.

The Hauck Venturi Oil Burner secures a thorough mixture of the air and atomized fuel oil at the mouth of the burner. It is correctly proportioned to the oil and steam or air pressures available, is accessible for purposes of cleaning and inspection, and can be conveniently removed from the furnace without affecting the operation of any other burner served by the same piping system.

Reducing, neutral and oxidizing flames are readily obtained merely by manipulating the oil and air valves. The furnace atmosphere is thus closely controlled.

Combustion can be made to take place close to the burner nozzle. Oxygen consequently cannot come into contact with the steel. This results in less scaling. Decarburizing of the work is reduced, and there is less spoilage and greater uniformity of product.

Close control of temperature is accomplished with ease and certainty. The temperature of the furnace is controlled through two standard valves. The labor and attention required are a minimum.

Uniform combustion conditions and ready, exact and simple temperature control increase the efficiency of production. Fewer demands are made upon skill and judgment in the handling of the furnace, and more time and attention can be devoted to the work itself.

The Hauck Venturi Oil Burner is simple to instal and easy to operate. The efficiency of the burner is high and is adaptable to a wide range of work.

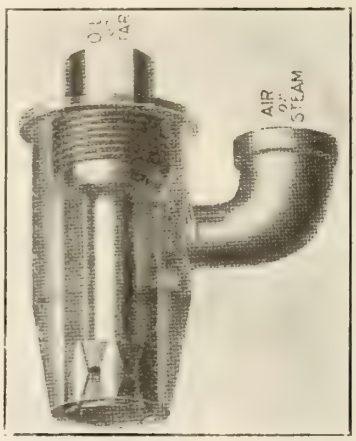

FIG. 1.

The real efficiency of the Hauck Venturi Oil Burner lies primarily in the fog-like atomization it secures, even with by-product tar, and furthermore in the greater convenience it offers in cleaning, adjusting and interchanging parts. It insures that refinement and control of the heating process which is so necessary in modern heat treatment work.

HEAT OF DISTILLATION OF COAL

J. D. Davis, fuels chemist, and Palmer B. Place, junior analytical chemist, of the Pittsburgh, Pa., experimental station of the Bureau of Mines, have developed a precise method for the determination of the heat of reaction of coals during carbonization. Typical coals have been studied for reaction heats over ranges of temperature in which primary decomposition products are formed. The investigation is now being extended over higher temperature ranges where, according to theory, reaction heats should be largely endothermic.

SELF-FITTING KEYS

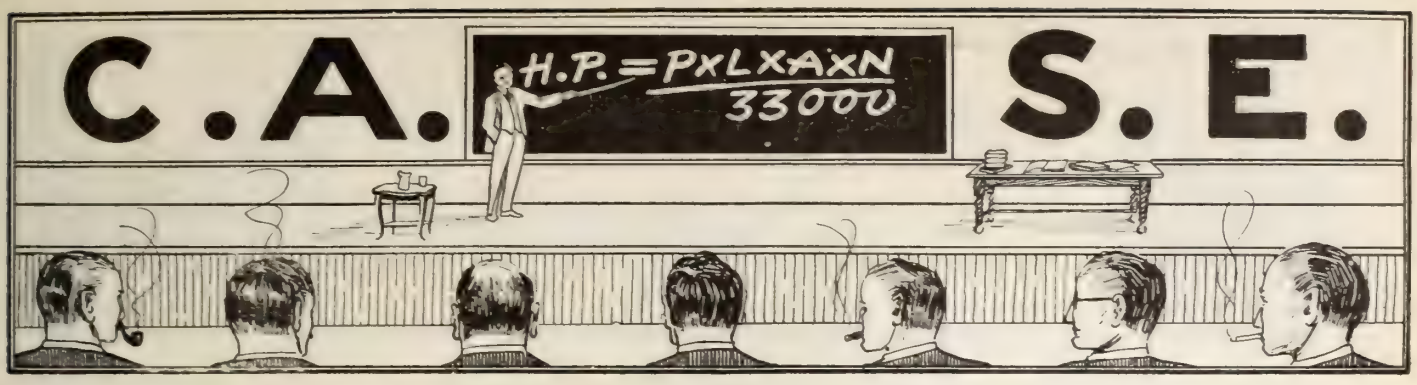
To facilitate the rapid fitting of keys a special type, capable of making its own fit in the keyway by shaving the sides of the latter as the key is driven in, has recently been placed on the market. Owing to the fact that the section of the keyway in the shaft and that in the hub are seldom in accurate alignment a certain amount of fitting is usually necessary. In making this special key a tough chisel key is used for the key, which is ground to a size slightly larger than the nominal keyway width. One end of the key is provided with a cutting edge and chip recess. Ahead of the recess is a pilot a little smaller than the keyway so that it fits the latter and guides the key. When installing the key the pilot is entered with the cutting edge on the side and driven home with a hammer or sledge, depending on the size of the key. On the smaller sizes the cutting edge is placed on the one side only but on the larger sizes double cutting edges are used. Special keys with three cutting edges may be obtained if desired. These keys are made in a wide range of sizes and are made by Smith and Serrell, Newark, N. J.

THE OSCILLOSCOPE

With engines or any other machines of large size running at from 50 to 100 revolutions per minute it is a simple matter to observe with the naked eye any irregularity of working that may tend to impair the efficiency, but in modern machinery where speeds of thousands of revolutions are made, undue vibrations or variations in the running cannot be detected.

The optical phenomenon, known as "Persistence of Image" has been utilized in the Elverson Oscilloscope. This is an apparatus for slowing down to the eye any high-speed machinery which it is desired to examine under working conditions. Not only may the machinery under examination be made to appear to be running at apparently one hundredth part of its normal speed, but it also may be made to appear stationary to the naked eye at any point in its cycle of operations, although actually it is moving at its normal speed. It is possible, therefore, to observe any irregularity or vibration which may be taking place and detracting from the efficiency of the plant under investigation, whether it is the finished product or the production of laboratory plant. The oscilloscope deals with all forms of motion, rectilinear, rotary, or cam motions, however intricate, and all problems of vibration, enabling it in the last

(Continued on page 39)



POSSIBILITIES OF THE POWER PLANT ENGINEER

The Editor, Power House:

Will you kindly permit me to make a few comments on the above subject in connection with your article under the above heading in Nov. 20 Power House. It goes without saying that engineers' pay is small on the basis of ability and effort required. But what is the remedy? You suggest organization but not such as is given by the unions. How would organization, such as the doctors have it, serve the purpose? We must not call their organization a union, that is too plebeian a term, but what is the difference between their methods and those of the most autocratic labor union that could be imagined? And they get there.

You mention the C. A. S. E. but do not advise anybody to join it. Possibly this is an oversight, or possibly the printer is to blame, so I will supply the deficiency by advising every engineer to join the C. A. S. E. I am not claiming that the C. A. S. E. is where it ought to be when its age is considered, but you must admit that an association is just what its members make it, almost without exception. Neither am I going to say that the fault has been in the leadership, because the leadership of a good leader may be queered by the efforts of a clique led by an ignorant member of the ward politician type. You are aware, no doubt, that the C. A. S. E. emphasizes education, and that coincides with your idea of what an organization of engineers should do. Not only do we emphasize education but I believe that I am not exaggerating when I say that we are accomplishing something along that line. I think that I can guarantee that a second class engineer can get all that he can carry away (in his head, I mean). More than that, I believe that first class engineers are learning something. It has not always been so however. During my membership in Toronto No. 1, for the past three and a half years, I have found that until recently it was difficult to accomplish anything of an educational nature, many of our meetings reminding me of Kipling's Bandar-log. But that has changed. The members are becoming more interested. There is more pep shown at the educational meetings; more questions are asked and there is more discussion. Not only is more interest taken in the meeting but the association is growing; over twenty engineers have joined since Aug. 1. The advantage of increased membership is being better understood. Increased membership means increased attendance and when the attendance is large enough it can be divided up into classes and graded instruction given, which will be an advantage because there is no doubt that much of the matter that is put on at the meetings is pretty heavy for some members.

To be sure, there are engineers who scoff at anything educational but they will learn their mistake when they try an examination. They will be weeded out and a bunch of them will some day be asking for special consideration because of their length of service—they will not be able to pass the examination.

Again, I advise every engineer to join the C. A. S. E. We are not running an engineer factory but we are helping each other and the stronger we are in numbers the more we can help.

R. McLaren,
160 Dovercourt Road,
Toronto.

EVAPORATION LOSSES OF OIL IN TANKS

In a general study of evaporation losses of petroleum being made by the Bureau of Mines, Ludwig Schmidt, junior chemical engineer, has arranged with one of the larger refining companies to conduct a series of tests to determine evaporation losses in 55,000-barrel tanks. Regular monthly gauges will be made and samples of the oil collected in order to determine the change in the quality of the oil during storage. It is later planned to extend this investigation to include water-sealed tanks. Arrangements have been completed for conducting a series of tests in the Tonkwa, Oklahoma, oil field. The crude produced in the Tonkwa field ranges from 42 to 44 gravity and contains approximately 40 per cent. gasoline. Due to the fact that this crude is very volatile the producing companies are anxious to obtain information as to the saving that can be made by the installation of gas-tight tanks. A number of such tanks are already in use in the field, but refining companies are anxious to obtain information as to additional precautions that should be taken in order to reduce evaporation losses.

C. A. S. E. MEETINGS

To the Editor:

In reference to the letter written by Mr. Brown published in the "Power House" on the 5th inst.

He outlines the good work offered by the C. A. S. E. for the benefit of its members, he also criticises many for not taking advantage of the same by failing to attend its meetings, but there are one class of men he fails to mention, namely, those employed of a night. For these members to attend the meetings would mean considerable expense to them, as many would have to forfeit the night's pay, also it would not always be convenient for them to be relieved of their duties. Would Mr. Brown explain how these men are to obtain some of these benefits.

I would suggest that some well-informed member, explain how these men could attend some of the lectures on engineering given in the day time at some of our technical schools and colleges without them having to enroll as regular students.

Also if some of the members of the C. A. S. E. whose name appears in articles published in outside papers would use the "Power House" as their mouthpiece for their views it would receive much more appreciation, also criticism by their fellow members.

I would like to hear some other members' opinions of the same subject.

E. H. Perkins.

Quebec, Que.—There has been considerable activity in the pulp and paper industry in Canada lately. Michigan interests are negotiating with Kingston, Ont., with the view of building there a pulp and paper mill. The Premier Paper and Power Co., of Hartville, N. S., is about to instal a standard newsprint machine with a capacity of 15,000 tons a year. The average daily production of the Abitibi Power and Paper Co.'s plant during August was 462 tons, and on the 29th of the month it reached as high as 494 tons. The groundwood pulp mill of the Backus Brooks Company, near Kenora, Ont., is also well under way. Work has started on the new 13,000 000 plant of the Wigwam Pulp and Paper Company, at Elko, British Columbia.

OUR QUESTION BOX

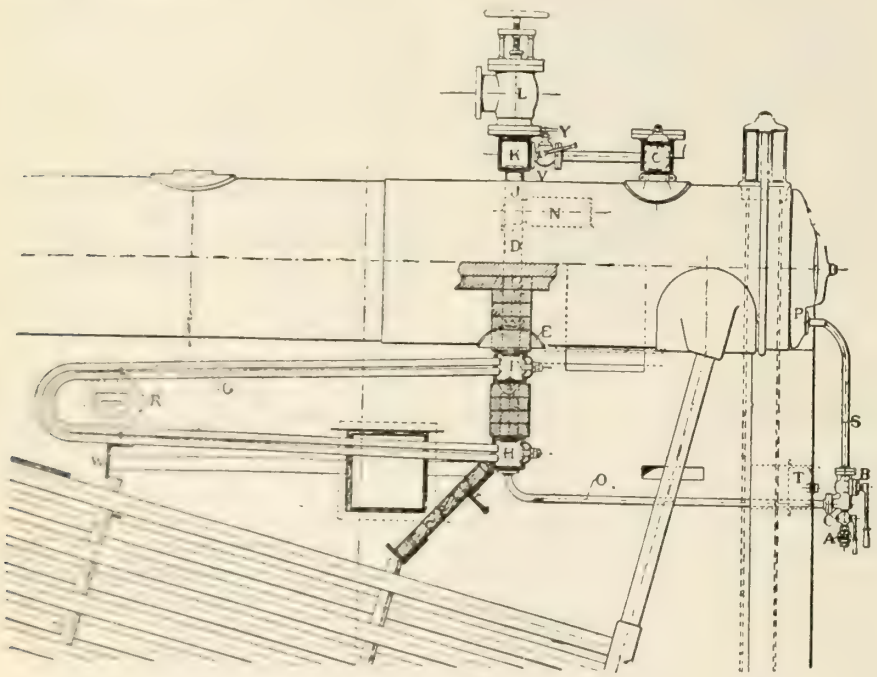
Questions are invited from readers regarding power plant operation and difficulties encountered

FLOODING SUPERHEATERS

Question:—Will you please answer the following question through the next issue of Power House:

What connections are necessary to operate a superheater flooded; also what extra precautions are necessary to follow when changing from and to superheated or flooded conditions; water tube boilers, b. h. p.?—H. E. I. G.

Answer:—We do not know the arrangement of piping and fittings you have in connection with your superheater, which we presume to be a B. & W. type. It might therefore be advisable to fully describe this apparatus with a sketch.



The Babcock & Wilcox Patent Steam Superheater (Fig. 1) consists of a solid-drawn steel tube bent into U shape, and connected at both ends with boxes or manifolds (F and H), one of which (F) receives the natural steam from the boiler through the draw pipe (N) and inlet pipes (D). The other (H) receives the superheated steam after it has traversed the superheater tubes (G) delivering it through pipes (J) and cross-box (K) to the stop valve (L) placed above the cross-box. Handholes are placed in the manifolds opposite the ends of the superheater tubes to facilitate inspection.

The flooding arrangement consists in a connection with the water space of the boiler drum; by means of the larger of two cocks (B) and connecting pipe (S) water can enter the lower manifold (H) and fill the superheater to the water level of the boiler. Any steam formed in the superheater tubes is returned into the boiler drum, through the collecting pipes (D), which, when the superheater is at work, convey saturated or natural steam into the upper manifold (F). Prior to opening the stop valve (L) when a superheater has been flooded, the water is drained away from the manifolds of the pipe (O) and the smaller cock (C). A sight glass (A) is attached to the outlet of the small cock to show when all the water has been blown out. The superheater is placed in a position where there is practically no deteriorating condensation of the gases, and where the temperature is sufficiently high to ensure the steam receiving from 100 to 150 degs. Fahr. of superheat. It is not subject to the immediate action of the fire, as the furnace gases must first pass through the front part of the boiler, which comprises a considerable heating surface. Assuming the boiler to be in regular work, and the firing even, no great fluctuation in temperature can take place where the superheater is fixed. It is readily accessible for examination, and for the renewal of tubes. There are no flanged joints, all the tube joints are expanded. Expansion is provided for by the tubes being free at one end, and by the manifolds not being rigidly connected with each other. Prevention against overheating during steam raising from cold water after cleaning, etc., is ensured by the arrangement for flooding with boiling water, and using the superheater as part of the boiler-heating surface.

* * * *

NUMBER OF LAMPS

Question: I would like to know how many lamps of 100 watts, or how many of 60 watts, could be carried on a circuit the switch of which can carry 50 amps at 110 volts?

Answer: A 100 watt lamp at 110 volts takes practically one ampere. You could therefore carry between 50 and 55 lamps of 100 watt. A 60 watt lamp at 110 volts takes about one half ampere so you could carry approximately 100 lamps of this size on the circuit.

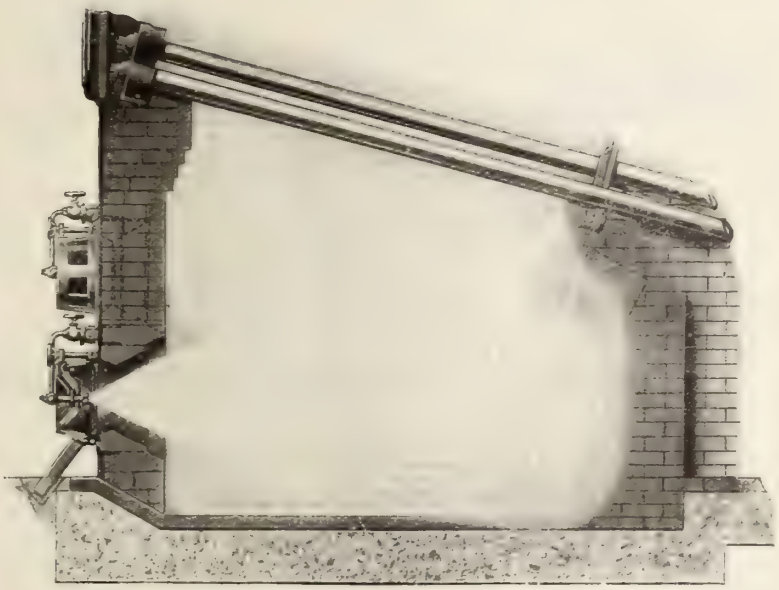
DIGEST

It is obvious to the constant reader of a good engineering journal that a great many ingenious ideas have been thought out and described through the correspondence section. Many of these ideas would be of considerable value if the idea suggested was developed and perfected by some experienced and skilled mechanic. I have seen sketches and read descriptions of home-made equipment, in this section of the journals, which to my mind would be anything but satisfactory in actual use, but on the other hand, perhaps others have seen defects in some of the ideas I have submitted, which looked quite in order to myself.

Simple home-made contrivances can be used with little loss and no great objection, but these could never be compared with the commercial apparatus that is designed for efficiency and some special purpose, such as water-heaters, oil filters, etc. Often an engineer will fail to persuade his employer to buy some piece of apparatus which the engineer is convinced will lower costs, lessen labor, and increase efficiency. As a last resort he attempts to set up a device of his own make, in an endeav-

(Continued on page 39)

BABCOCK & WILCOX
OIL BURNING EQUIPMENT



Babcock & Wilcox furnace for burning oil fuel only

The merits of oil as a fuel for steam generation, in places where its cost compares favorably with coal or wood, are, briefly, the following:—

1. An increase in boiler efficiency, owing to the clean condition in which the boiler heating surface can be maintained, and the completeness of combustion obtainable with a good system of oil firing.
2. A constant and equal distribution of heat in the furnace, and, as there are no fire doors to be opened, the cooling effect of a large volume of air passing over the furnace is avoided.
3. A reduction in the cost of handling the fuel, as this can be done by a pump; and a large reduction in manual labor, the firemen not being required as they would be for ordinary fuels. One man can regulate the burners of a considerable number of boilers.
4. No wear and tear of grate bars.
5. No dust, no ashes, and no clinker.
6. When once arrangements have been made, the storage of oil fuel is simpler than the storage of coal, and oil does not deteriorate.
7. The control of the steam production is easier, more effective and more rapid than with solid fuels.
8. Instantaneous ignition, and extinction of the fire.
9. No smoke.

The three main systems for burning oil fuel are: —

1. That in which STEAM is used as a spraying or atomizing agent.
2. That in which AIR is used for this purpose.
3. That in which the oil is atomized mechanically by PRESSURE.

We would be glad to go into details with a prospective purchaser.

BABCOCK & WILCOX, LIMITED

HEAD OFFICE FOR CANADA - COLLEGE ST. (ST. HENRY), MONTREAL

TORONTO OFFICE, BANK OF HAMILTON BUILDING

The Operators' Point of View

BOILER HEAD DEFECT

W. McGheen

An engineer noticed a spray flowing out through the iron on the near head of the boiler, a close examination with pressure off failed to show any flaw, the spot was marked while the boiler was under pressure and later a hole was drilled and properly plugged at the marked spot. This cured the defect, there was no sign of pitting or grooving, the conclusion arrived at was the probability that a small piece of foreign matter had been left in the plate at the point where the blowing occurred, it is difficult to imagine any other cause. This engineer had constant trouble with the burning of the rear hand hole bolt, after the hole had been plugged this trouble was greatly lessened, probably the moisture from the spray had much to do with the burning, this is a tip to others who may be having burned bolt trouble. It pays to examine hand hole plates carefully while the boiler is under test pressure, and make sure the joint is absolutely tight. Some time ago, I was looking over a boiler, the pressure carried was 95 pounds gauge, the 2½-inch blow-off was ordinary weight iron pipe. The man in charge said he had been using this kind of pipe for years and never had an accident, he is lucky. Nothing less than extra heavy pipe should be used for this kind of work, the person who does not know this fact should not be allowed any authority in a boiler room. Besides using heavy pipe, precaution should be taken to protect the pipe to some extent from the intense heat by using a good cover. Sometimes using an asbestos covering on the rear hand hole plate bolt will protect it to a large extent during a monthly run. Such bolts on the ordinary steam boiler are not expensive and it is good business to use a new one each clean out time, usually once a month.

BOILER FEED

By Crippen

I believe it is a good idea to provide two ways by which the water may be fed to steam boilers. To do so, just outside the main feed line from the pump one could put in a tee and run a line from it to the rear end, connecting with the blow-off pipe, and using a cut-off valve and a check valve the same as on the [illegible]. Should one become sediment or scale-choked this extra line can be used until time can be had for making the necessary repairs. Such a pipe may also prove of value to clear the blow-off pipe should it become blocked up, without shutting down the boiler. By closing the valve in the main feed line the full pump pressure can be turned into the blow-off pipe to blow the collected sediment into the boiler, then opening the blow-off valve to get rid of the loosened dirt. It is no uncommon thing for a blow-off pipe to become closed with loose scale when the water contains considerable foreign matter, even when the valve is opened several times during a 24 hour run. The instructions may be to open the blow-off valve every few hours but instructions are often not adhered to. It means a big expense, to say nothing about the annoyance, when a fire has to be drawn and pressure lowered to clear a blow-off. The steam boiler in a power plant is a mighty important piece of apparatus and often receives little attention so long as things appear to be going along O. K. A boiler to generate the greatest amount of steam from the smallest amount of fuel must receive very careful attention as to cleaning internally and externally, time allowed for cooling and steam raising, etc. Of course, the large concerns usually have enough boilers so that one or two can be taken off at a time and the proper time allowed for cooling and cleaning, but a great many of the smaller plants have no such ideal condition. The result is the boilers are apt to get some severe abuse. When this happens it is not well to always lay the blame of ill-used boilers upon the engineer, often he is compelled to do as he is told or to look for another position. A man with a wife and young ones to support will hesitate to throw up a situation, for often it is by no means easy to find a new one.

ONTARIO STEAM BOILER ACT

A joint deputation from the Canadian Association of Stationary Engineers and the International Union of Steam and Operating Engineers interviewed by appointment officials of the Ontario Government with reference to suggested improvements in the Steam Boiler Act. The Government officials present were Mr. J. H. H. Ballantyne, deputy minister of labor; Mr. Burke, chief inspector of factories and Mr. J. M. Brown, chief examiner of engineers. The deputation urged on the deputy minister the necessity of bringing all boiler inspection under one department, and also the appointment of more inspectors under the Board of Examiners so that the law with regard to certificates could be more fully enforced.

The deputy minister listened courteously to the deputation and promised that their requests would be given consideration.

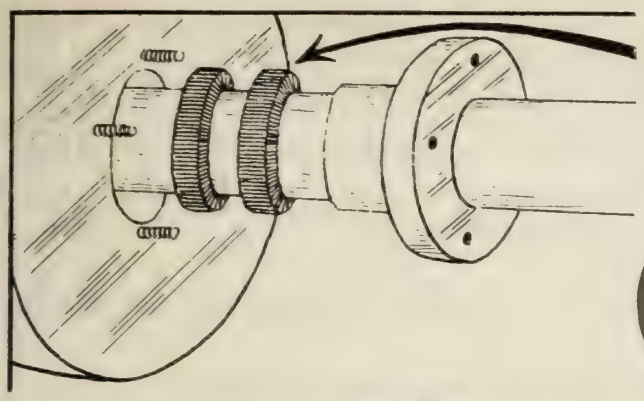
PISTOL-GRIP HACKSAW FRAME

A pistol-grip hacksaw frame has recently been offered to the trade. Springs are used to provide constant tension on the blade. This feature enables the blades to be changed quickly. The adjusting pawl is set down inside the frame as low as possible. Strong but light steel tubing is used for the back and all steel parts are nickel-plated. The blade may be set to cut in any one of four directions by means of the wing nut. The frame is 3⅜in. deep and blades of from 8 to 12in. may be used. The hard rubber, checked handle provides plenty of finger room and gives a comfortable grip for the operator. These frames are made by the L. S. Starrett Co., Athol, Mass.

Pistol-grip Hacksaw Frame.

ELEVATOR LUBRICATION

The problem of lubrication of elevator machinery is becoming of considerable importance to the engineering profession to-day. The ever-increasing demand for elevator service, as higher buildings are becoming more and more necessary to house the executive offices of our industries and store their products, has eliminated the heretofore popular idea that elevator machinery, especially of the electric type, could be lubricated in much the same manner as other types of gearing and general motor driving mechanisms. There are certain pertinent operating features which prevail that demand considerable cooperation between the elevator engineer and lubricating oil manufacturers, and careful attention must be paid to these details.



Raybestos PACKINGS

"They Wear Longer"

The Engineer Wants Raybestos Packings because he knows they are Heat-proof and Acid-resisting.

Use Raybestos Packings for Pipe Flanges, Cylinder Heads, Piston Rods, Valve Stems, Plungers, Boiler Manhole and Handhole Plates—and all packings for Air, Steam, Acid, Oil or Ammonia.

The consistent use of Raybestos Packings will result in substantial economy—"They Wear Longer."

PULVERIZED FUEL HANDLED BY COMPRESSED AIR

Some further details regarding the equipment to be used in handling the pulverized coal at the New Cahokia Station of the Union Electric Light & Power Company, St. Louis, Mo., have been announced.

Among these, the method of weighing the fuel and conveying it from the pulverizers to the boilers is of unusual interest. Below the floor level of the pulverizing room will be placed a series of five blowing tanks, which serve an equal number of twin pulverizing units. These blowing tanks will rest on platform scales, the dial of which will indicate to the operator in the pulverizing room the amount of fuel in the tank.

The fuel will feed into these tanks by gravity, as desired, from the pulverized fuel bins in the pulverizing room. Each charge will be automatically weighed, and then elevated about 75 feet, by compressed air, through 4-inch pipes. A simple system of switching valves and parallel distributing mains, cross connected, enables any blowing unit to be discharged into any of the eight enclosed storage hoppers in the boiler house. These hoppers serve the four pairs of boilers, each of 1,780 h.p., comprising the first group of boiler units to be install-

The fuel requirements for the first group of units are estimated at 1,000 tons in sixteen hours. This equipment was selected on account of its cleanliness and freedom from mechanical complications which would be liable to interrupt service. The contract has been awarded to Quigley Fuel Systems, Inc., of New York.

BELT SPEED

Belt speed is determined by the rim velocity of either the driving or the driven pulley. It is equal to the diameter of the pulley times 3.1416 times the revolutions per minute of the pulley. If the pulley diameter is given in inches, divide the answer by twelve to get the speed in ft. per min. Example: 14 in. dia. pulley running 600 r.p.m.

$$\frac{14 \times 3.1416 \times 600}{12} = 1675 \text{ f. p. m.}$$

Avoid crossed belts on short center distances. Avoid crossing wide belts anywhere. If crossing is necessary, see that the rubbing of the belt surface does not have a tendency to open up the laps.

Use a wide enough pulley so a small amount of belt irregularity does not make it run off. Allow at least ½ inch on machine pulleys, and 1 inch or more on countershaft and lineshaft pulleys. Use crowned pulleys where possible.

If possible, use a horizontal belt with large center distances and the pulling side at the bottom. In a horizontal drive, the slack side of the belt at the top of the drive increases the belt contact.

To obtain a given amount of power, better use a narrow belt running at high speed than a wide belt at low speed.

Where possible, use a belt speed of 3,000 ft. per minute, but no more than 3,600 ft. per minute.

Smart-Turner Machine Co., Hamilton, report the following recent sales: Two No. 4 double suction centrifugal pumps for the Abso-Pure Ice Co., Hamilton, few small triplex power pumps, ordered by Department of Marines & Fisheries, for delivery to the Dominion Lighthouse Depot, Prescott. A No. 4 belt-driven centrifugal pump, ordered by H. F. Routley, Toronto, for quarry service near Caledonia; one 4½ x 2¾ x 4 duplex, packed-piston pump, to Standard Paving Co., Lindsay; a pair of 8 x 10 x 12 simplex vacuum pumps; an automatic feed pump and receiver equipment with motor-driven centrifugal pump and two motor-driven centrifugal circulating pumps for the Essondale Asylum, Vancouver, B. C., and a 5½ x 6 triplex power pump for Vipond-North Thompson Mines, Timmins, Ont.

TENSION AND WORKING STRAINS

(Continued from page 30)

slack strand 60 pounds in order to give the necessary 60 pounds of pulling power, and the bearing must stand a load of 180 pounds, just twice the load in the other case noted above.

The maximum load on the fastener in each case is the tension of the tight strand of the belt. In the extreme case of the poor belt described, the fastener would have to withstand 120 pounds per inch of width. Efficient belt hooks under many tests, have shown a strength never less than 400 pounds per inch of belt width and it is easy to understand why they carry the full belt load and do not put out. Even in a poor belt carrying its rated load (which as a matter of fact is not possible with such a poor belt) there is a margin of safety of 400-120 or 280 pounds.

In the chart the length of the bars represents the total strength of efficient belt lacing in a one-inch belt. The black area shows the proportion of this which is actually required to transmit the rated horse power to the belt, while the white area shows the margin of strength remaining as a safety factor.

THE OSCILLOSCOPE

(Continued from page 32)

case to show the periodicity with regard to any shaft at once, and without calculation, and in the case of compound vibration to analyse it into its component constituents and resolve those constituents in such a way as to determine at once their origin and frequency.

The advantages of such a machine says "Steam," are only too apparent and it may be that it will give the same information regarding the variations of stresses in machines as the indicator gave of the working and variations of pressure of steam in an engine cylinder.

This machine is now being demonstrated by Messrs. H. Kennedy & Co., 46 Gordon St., Glasgow.

DIGEST

(Continued from page 34)

or to show better results or to influence his employer to purchase the factory-made article.

Perhaps there would not be so many defects in home-made equipment for power plant use if the experimenters were familiar with the latest improved appliances on the market. There is no excuse for any engineer to be ignorant of such knowledge. All he has to do is to systematically read his engineering journal, especially the advertisements. If he does not, there will be many important improved apparatus which he may never hear about.

There are many engineers who value their classified files of clippings taken from the advertisements equally as much as technical matter taken from their text-books.

James Noble.

Calgary, Alta.—With oil developments in Northern Montana now being undertaken on a wide scale, various American companies are taking steps to secure extensive leases on the Canadian side of the line. One concern has obtained 31,000 acres in Southern Alberta, and others are considering the leasing of other substantial acreages.

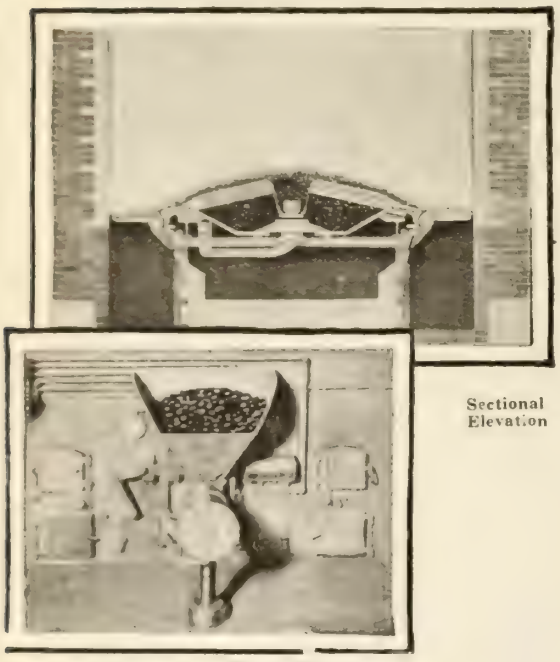
PLAN TO EQUALIZE AIR PRESSURE

When large quantities of air are used underground, it often happens that there are wide fluctuations in the amount needed at any one time. A plan to keep the pressure uniform and to provide additional storage is in use at a plant near Bisbee, Ariz. At the top of the hill, which is about 200 feet high, is a reservoir. Into the bottom of this a large pipe is connected, which follows the contour of the hill down to the base, where the air receivers are situated. This pipe acts as an auxiliary receiver. Under conditions of small air reserve it is filled with water. If the amount of air on hand increases, the water is forced up the pipe and into the reservoir. When greater demands are made on the available supply of air, the water falls in the pipe and so keeps the pressure uniform.

In developing hydro-electric power on the Oswegatchie River in northern New York a wood-stave pipe is being constructed twelve feet in diameter and more than two-thirds of a mile long. The staves are of Douglas fir brought from the State of Washington. They are 3½ inches thick and are able to sustain a head of water of 140 feet.

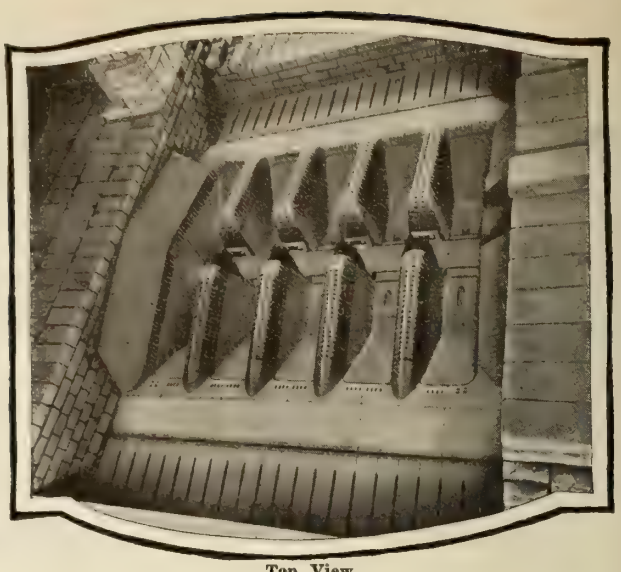
The Imperial Oil Co. has just completed two large storage tanks at Sydney, N. S. This will form part of the plant now being erected. These tanks have a capacity of 10,000 gallons each.

The Coal is Underfed from Start to Finish



Sectional Elevation

Front View



Top View

AS A RESULT of the revolutionary *"lateral retort"* principle the advantage of the multiple retort stoker—high capacity and efficiency—are combined with the advantages of the side-cleaning stoker—lower first cost, reduced installation cost, and adaptability to old boilers.

The *"Lateral Retort"* Stoker is not claimed to be a substitute for multiple retort stokers—but—it does bring the advantages of multiple retort stoking to the plant that otherwise would install an inferior stoker.

The illustrations, opposite show how the truly underfeed effect is accomplished. The coal is first underfed into the central retort by means of a main ram. It is then underfed—always underfed—into the *"lateral retorts"* by means of an auxiliary steam cylinder which operates lateral pusher rods.

There is only one simple unit for distributing fuel in five or more *"lateral retorts"* and, since this feeding mechanism is controlled independently of the main fuel feed, ideal distribution is possible under all conditions.

A trench 16 to 18 inches below the floor line is sufficient excavation for ash pits. This reduces installation cost and makes the stoker adaptable to boilers already in service. The many good points of this stoker are covered in greater detail by a new bulletin. Where shall we send it?

BAILEY Fluid Meters

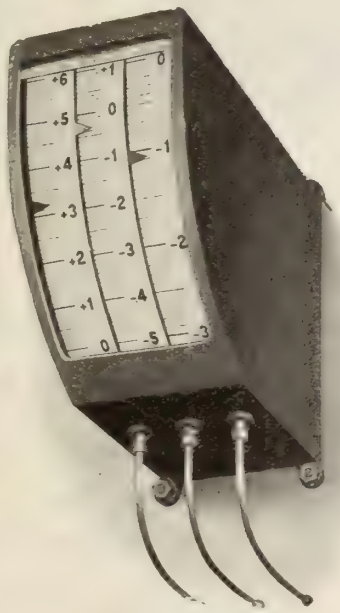
Unless you know exactly how much steam you are using to heat your plant—unless you are able to keep comparative records — how can you know how near to the standard of practical operating efficiency your daily steam consumption approaches?

The Bailey Fluid Meter will give you all the information required for this check. It will indicate—and record for future reference — record and integrate Steam Flow, high or low pressure, with accuracy and with practically no attention.

The Bailey Fluid Meter is self-contained, portable and is made with capacity to suit each particular installation. It records rate of flow in any desired units on 12-inch, 24-hour, uniformly graduated charts. IT WILL SAVE ENOUGH IN A SHORT TIME TO PAY THE COST OF INSTALLATION.

BAILEY Multi-Pointer Gauges

Can be equipped with separate pointers to indicate scale readings of practically every factor of operation. Each pointer has a 10-inch motion over illuminated scale, graduated so that readings can be made at a distance of 20 feet.



All Bailey Products are made in Canada

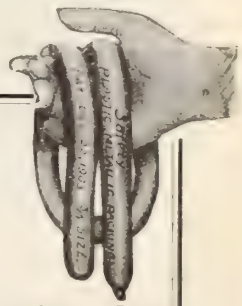
"SAFETY" PLASTIC METALLIC PACKING



Packing in Cotton Tubes.

This packing is made of an alloy of the FINEST ANTI-FRICTION METALS which, combined with the BEST LUBRICATING MATERIALS which always remain in the packing, make it practically **Self-Lubricating and Frictionless.** It is

GUARANTEED TO LAST THREE YEARS WITHOUT RENEWAL

In fact there are many Engines, Pumps, Compressors, Expansion Joints, Valves, etc., on which this packing has been in use for over 12 years with the very best satisfaction.

Let us send you further particulars also about our "Safety" Superheat Sheet Packing.

Packing in bulk.

Established 1899

STEEL MILL PACKING CO. - WINDSOR, ONT.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we willtell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

CURTIS ENGINEERING SPECIALTIES

Comprise a line of devices that have stood the test of years for the utmost in efficiency. They are built for dependable and enduring service. Scrupulous care in the selection of material and in construction, with adherence to the highest engineering standards, have won them a commanding position. The

CURTIS WATER-PRESSURE REGULATOR

will deliver water into service pipes at any desired pressure, regardless of any fluctuations of outside pressure.

Trouble with rust or clogging with sediment is prevented. Waste of water in domestic use by flying or spattering is avoided by the reduced pressure. This also prevents water hammer or concussion and prevents wear and tear on all packings and seats in valves and faucets, thus eliminating frequent plumbing bills. Adapted for use in pulp and paper mills, hotels, public buildings and dwelling houses. For ¾ in. to 2½ in. pipe, screwed. For 3 in. to 8 in. pipe flanged.

The Curtis Line of Steam Specialties contains many other notable devices. They are fully described in our No. 50 catalogue. Write for a copy.

JULIAN D'ESTE COMPANY
26 Canal Street, Boston, 14, Mass.

Stop Wasting Oil

The De Laval Oil Purifier returns to service lubricating oil or transformer oil which would otherwise be thrown out. Better still, its continued use constantly maintains the efficiency of such oils.

The De Laval does its work instantaneously, thoroughly and economically by centrifugal force. It is the modern method of making turbines and Diesels give longer and better service, and of prolonging the life of the oil used to lubricate them. It is the far more economical method of maintaining the dielectric strength of transformer oil.

No matter which of these tasks you give a De Laval—you can use the same machine for both—you have absolute assurance that the work is being done better and more economically.

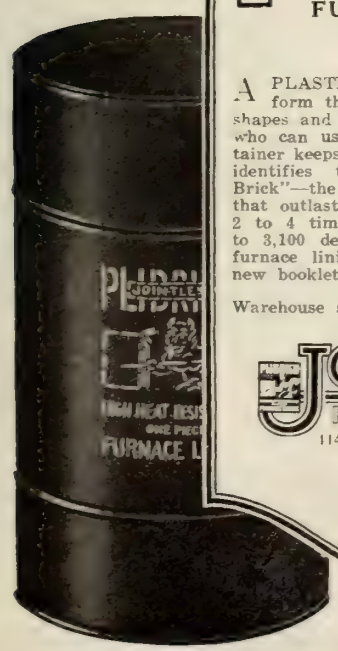
PLIBRICO is sold only in containers of distinctive appearance as shown below.

Ask for this Booklet



Here's *your* furnace lining

PLIBRICO
FURNACE LINING

A PLASTIC refractory in unbaked form that conforms to all furnace shapes and can be installed by anyone who can use a mallet. This steel container keeps it in perfect condition and identifies the only "Jointless Fire Brick"—the one-piece refractory lining that outlasts ordinary fire brick from 2 to 4 times and resists temperature to 3,100 deg. F. The way to better furnace linings is the subject of the new booklet. Where shall we send it?

Warehouse stocks in principal cities.

JOINTLESS FIRE BRICK CO.
1142 Clay St. Chicago, Ill.

ANDERSON

Pressure Oil Filter

By practical demonstration wherever they are installed these Filters have proven their great economic value in the purifying of lubricating and cutting oils and in drying the moisture from and filtering transformer oil. In many cases they have effected a saving of at least 50%. The Anderson is designed in various types in order to meet varying conditions.

I. H.C. 12 H.P. GAS ENGINE FOR SALE—ALL in good running shape, with 33-inch clutch pulley; will be sold reasonable on easy terms. Apply W. Harrison, & Son, R. R. 5, Guelph. When answering this advertisement, please mention this paper. P.F.H.

ABSOLUTE BELTING BARGAINS—BELTING every description; rubber hose, thresher supplies, tank pumps, pump leather feeds, canvas, McGill auto powers, special reduced prices; for quality and price, you can't beat us. N. Smith, 134 Adelaide west, corner of York, Toronto. When answering this advertisement, please mention this paper. P.F.H.

TAYLOR SAFES FOR SALE—RARE OPPORtunity to secure a safe at small cost. They are in splendid condition. **Inside** dimensions and prices are as follows: 15" deep, 2 ft. 6" wide, 3 ft. 11½" high, fitted with built-in compartment. Price $250.00. 18" deep, 2 ft. 8" wide, 4 ft. 5" high, fitted with steel compartment. Price $200.00. Apply Box 10, POWER HOUSE.

FOR SALE
Fuel Oil Storage Tank
10,000 GALS. CAPACITY.
This is a new tank. We have not yet taken delivery of it, and offer it at a very attractive price.
MR. VOGAN, The MacLean Publishing Co., Ltd, 143 University Ave., TORONTO.

Patterns **Machine Work**

Every Engineer, Mechanic and Electrical Worker will welcome this new master set. It will answer your problems
It will help you with your daily work.—A sure source of advancement and higher pay. Complete up-to-date information that is thoroughly and easily explained on every branch of modern engineering and electrical practice.
AUDEL'S ENGINEERS & MECHANICS GUIDES
4750 PAGES 8754 ILLUSTRATIONS $1 A MONTH $12 COMPLETE
These Guides tell you all about—
Theory, Practice and Operation of ALL Steam Engines; UNIFLOW and POPPET VALVE ENGINES, and LOCOMOBILES, Locomotive-Marine Engines; Turbines; Rotary Engines--the Indicator--Lubrication--PRACTICAL MANAGEMENT; GAS, GAS ENGINES--*Aeroplanes* and *Aviation*--HOW TO SELECT AN ENGINE. STEAM ENGINE rules and formulae. Steam Boilers; Heat-Combustion; Fuel and Flue Gas Analysis-CO2 Recorders-Construction of all types of Boilers,--Mechanical Stockers--Oil Burners--Setting--Chimneys--Mechanical Draught --HOW TO SELECT A BOILER--BOILER DESIGN based on A.S.M.E. BOILER CODE--OPERATION FIRING. Pipes, Fittings--Heating and Ventilation--Refrigeration--Cooling Towers --Condensers--Distilling Apparatus--Elevators--Cranes--Ropes and Cables--Splicing--*Practical Electrical Engineering* as an aid for engineers and electricians in obtaining a license--ready reference index, covering entire field of Modern Electricity.
SHIPPED TO YOU FREE
Not a cent to pay until you see the books. No obligation to pay unless you are satisfied. Send coupon now--today and get this new master set for engineers. Pay only $1 a month.
SEND NO MONEY
THEO. AUDEL & CO, 72 Fifth Ave., N. Y.
Please submit me for approval, AUDEL'S $10,000 MASTER SET FOR ENGINEERS & MECHANICS. Ship at once prepaid, the 8 numbers. If satisfactory, I agree to send you $1 within 7 days and to mail you 1 monthly until $12 is paid.

Reading Valve & Fitting Division
Bridgeport, Conn.

Tycos and Superheat

The problem of superheated steam lines is remedied when *Tycos* Indicating, Recording, Controlling Temperature Instruments are installed.

A *Tycos* equipped superheater becomes almost automatic. It features electric alarms for warning if either temperature or pressure raises or falls, along with complete pressure and temperature controls and recorders.

A more detailed description is given in catalog part one. Send for it.

KERR

"Guaranteed" Satisfaction

FORTY years' experience has shown us that Satisfactory Valve Service can be attained only by conforming to the most modern and approved practice in both design and construction.

It is this policy, together with the exercise of the greatest care in every detail of the work and the severe tests to which all our goods are subjected, that is behind the KERR Guarantee of Satisfactory Service—a guarantee that backs every sale of KERR Goods.

Columbia
Recording Thermometers

This advertisement is one of a series, each one of which covers one of the many "Columbia" exclusive features. In this way we believe we can best meet the inquiries we are constantly receiving for definite information.

THE ACTUATING MEDIUM

The actuating medium of the "Columbia" Recording Thermometer is Mercury, the standard basis of temperature measurement. Its superiority as the actuating medium of the industrial thermometer is attested by the fact that it is employed in all thermometers of the glass tube type where accuracy is essential. The most sensitive test thermometers and delicate clinical thermometers are mercury actuated. That is why mercury is employed in the "Columbia"—because it is the only substance having all the fundamental requisites necessary to measure temperature with absolute accuracy, being extremely sensitive and responding instantaneously to the slightest temperature changes. And the action of mercury is uniform. The record given by the "Columbia" can, therefore, be relied upon as being absolutely accurate and true.

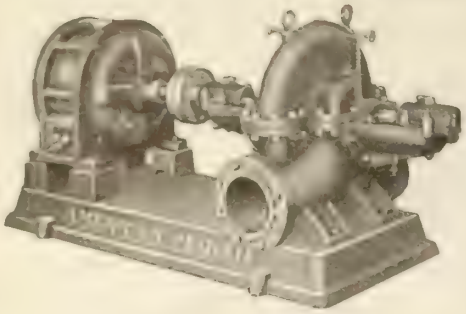
AMERICAN-MARSH PUMPS

Centrifugal and Direct Acting



Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The Line includes :

Boiler Feed Pumps	Jet Condensers
Air Compressors	Vacuum Pumps
Deep Well Engines	Condensation Pumps
Centrifugal Pumps	Sump Pumps

LONG ENDURANCE DETERMINES REAL ECONOMY

especially in rod and valve stem packing, working under present day conditions. To secure the economy of service a packing must be made of better materials than the average high pressure packings.

TRADE MARK

"PALMETTO" PACKING

REG U.S. PAT. OFFICE

is made to give long service under the very exacting conditions of high pressure, superheated steam and compressed air.

The amount of packing necessary to fill a stuffing box is so small that the value of it bears no relation to the labor cost of applying it, to say nothing of the loss of the engine or pump while out of commission.

The packing that gives long service is sure to be the most economical, no matter what its first cost.

If you don't know "Palmetto" let us send you, without charge, working samples to test for yourself.

BRAIDED for rods.
TWIST for small valves.

Morrison Injectors

A line with a record of big service

Morrison "Standard"

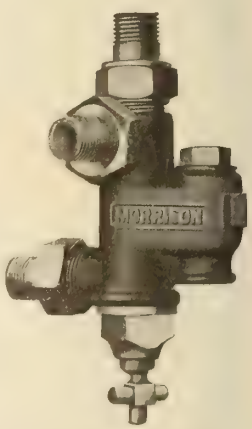
specially built and recommended for working pressures up to 150 lbs. per square inch.

The **Morrison** Injector has been in general use as an All-Round Boiler Feeder for over 25 years and has become one of the standard machines recognized by the trade for efficient and durable service. It acts as a Boiler Feeder under all the varying conditions of pressure and temperature limits. Our High Pressure Injector, in fact, will operate under a wider range of boiler pressures than any other device we know of; viz., from 20 lbs. to 220 lbs. per square inch.

Special Style

Right and Left. Standard and High Pressure.

Full particulars of these and the other Morrison Products will be found in the Morrison Catalogue. Send for a copy.



Morrison "High Pressure"

adaptable for satisfactory service on working pressures up to 220 lbs. per square inch.

Regrinding Valves that give satisfaction

Fig. 425.
"RELIANCE" REGRINDING VALVE (Sectional View)
Suitable for working steam pressures up to 200 pounds per sq. in.

In "Reliance" and "Sterling" Regrinding Valves we offer a complete line of dependable valves of the regrinding type.

These valves are made from the very best materials and every detail of their construction is in keeping with the standard of workmanship which has made the name "JENKINS" a mark of valve dependability.

"Reliance" and "Sterling" Regrinding Valves are giving excellent service wherever installed.

Write for literature illustrating and describing these Jenkins Valves in detail.

Renewable "VALVE NICKEL" Disc and Seat

LUNKENHEIMER

"Renewo" Valves are the climax in the evolution of valve design from the old style soft seat valve for low pressures to the present day high pressure and temperature valve.

The "Valve-Nickel" **seat ring** and **disc** in "Renewo" Valves have unusual wear resisting qualities under extreme operating conditions. When wear does occur the seating surfaces can be reground or the **seat ring** and **disc can be renewed.**

With all other parts made of high-grade bronze, formulated for the duty each part performs, the life of the valves is prolonged indefinitely.

"Renewo-equipped" means permanence, and represents an investment unparalleled in point of value to the purchaser seeking the highest degree of efficiency and economy in valve service.

Booklet 535-DC lists and describes the full range of types, sizes and weights of patterns available.

Write for a copy.

A Merry Christmas

and a generous share of the prosperity which
it believes is coming in the New Year

Top view and sectional elevation of *"Lateral Retort"* Stoker.

Underfed throughout

—multiple retort stoking without multiple retort complications

THE *"Lateral Retort"* Stoker has made possible, for the first time, a multiple retort effect in a simple side-cleaning stoker—a stoker that costs far less than a multiple retort stoker; that requires no expensive provisions for installation; that is adaptable to old boilers because no basement space is required for ash pits.

How the ingenious *"lateral retort"* principle insures multiple retort stoking in a simple stoker with only a few rugged moving parts, is shown by the illustration above. The arrows tell the story. Coal is first underfed to the large central retort by a steam driven ram. It is then underfed to the several *"lateral retorts"* by means of simple pusher rods, all of which are operated by a single auxiliary steam cylinder. From its entrance into the main retort until it reaches the dump plate, the coal is always *underfed*—an advantage heretofore possible only in stokers of the multiple retort type.

The *"lateral retort"* arrangement also provides a large fuel capacity for meeting peak loads and overloads. Eighteen inches is sufficient excavation for ash pits and consequently the stoker is ideal for low set boilers.

Learn how the *"Lateral Retort"* Stoker meets a hitherto unfulfilled need. Write for the bulletin.

Valves that set a High Standard

Mueller Valves are not only known as good serviceable valves but invariably set a standard by which other valves are judged.

Positive in action. Designed so that the stem threads are protected by valve bonnet when open. Added strength is given by the inside threaded bonnet.

There is Strength in MUELLER Valves

The Mueller design provides a heavier and stronger valve.

Each valve must prove itself in severe tests before it leaves the factory—a safe, dependable valve in any kind of service.

Send for data on the valves in which you are interested.

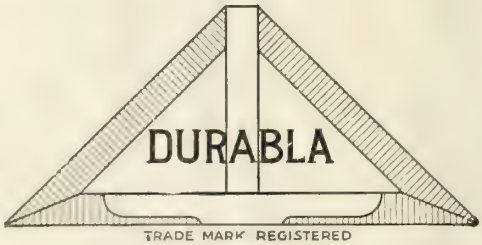
Perfect Service Gasket Material

Guaranteed to make a Tight Joint wherever a Permanent Gasket is required.

Place DURABLA in the next joints you make and be insured against a costly shutdown.



Strength; Goodness; Quality—these features distinguish durable Gaskets.

DURABLA Sheets can be rolled and unrolled; it never dries out or opens up.

DURABLA Compressed Asbestos Fibre Gasket Material is a guaranteed product that can be used as a standard for all Gasket work. DURABLA Gaskets make tight joints on Steam, Water, Oil, Ammonia and Acids at all temperatures and pressures.

DURABLA is not affected by vibration or condensation. It will not burn out, blow out or pulp at the points. Let us send you a trial sample. Made in stock sizes 36 in. wide x 144 in. long, and 48 in. wide x 144 in. long, in thicknesses of 1-64, 1-32, 1-16, 3-32, 1-8.

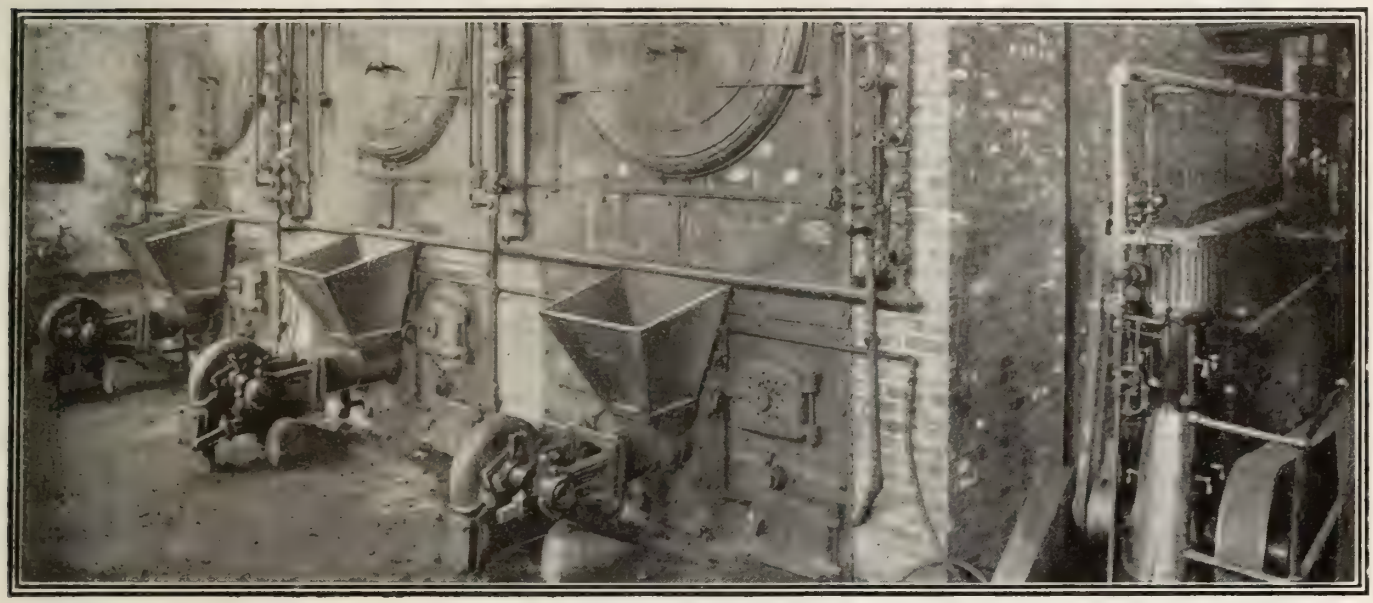
Detroit Single Retort Underfeed Stokers can be Installed Profitably Under Tubular Boilers



Tubular Boilers fired by Detroit Single Retort Underfeed Stokers

Take the case of two power plants of approximately equal size and capacity. One of them had hand-fired furnaces, under tubular boilers, and the bad conditions of this type of firing had a psychological effect on those working in the boiler room. The place was in a generally ill-kept and unsatisfactory condition. The other plant, which also had tubular boilers, was equipped with mechanical stokers, and, perhaps, because the attainment of efficiency in combustion stimulated the firemen to better work all around, the boiler room was in first class condition. The first plant was using one and one half times as much coal as the second, and because of lack of efficiency in the boiler room, the cost of steam generation was actually twice the cost of production in the second plant.

When stokers were finally installed in the inefficient plant it was found that a cheaper grade of fuel than had previously been used could be burned, and that, due to the uniformity with which the stoker fed the fuel, the proper proportioning of air for combustion, the absence of large amounts of excess air, etc., it was possible to maintain a uniform boiler efficiency of approximately 70 per cent, whereas 55 to 60 per cent had been the rule before. The same amount of steam was generated with considerably less coal.

With the installation of the stokers, a transformation took place in the boiler room. The firemen began to display a hearty interest in their work. As a net result the cost of producing steam in the plant was reduced something like 50 per cent.

Ask for your copy of "Cutting the cost of Producing Steam." It describes Detroit Single Retort Underfeed Stokers and tells the story of the two plants mentioned in this advertisement in detail. Request Bulletin 238

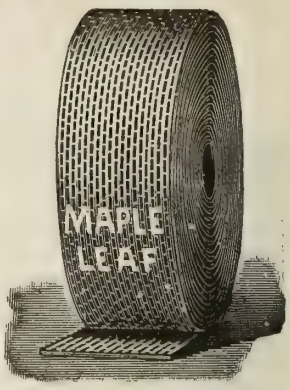
Dominion Belting Company, Limited

Hamilton, Canada

Sole Manufacturers of the celebrated "MAPLE LEAF" Brand Stitched Cotton Duck Belting and Belt Dressing.

The demand for our products has steadily increased because the standard of quality has been maintained.
We make only one grade, the best that can be produced.



"MAPLE LEAF" is the strongest, truest running, most economical and efficient belt on the market for transmission of power, conveying, etc.

Being thoroughly waterproof it is suitable for running in wet or dry places. **"MAPLE LEAF"** Belt Dressing is different to others offered in that it is equally good for all kinds of belting, leather, rubber, or Balata, as well as our own make.

Write us for prices, and if desired we will be pleased to furnish samples and further information.

A trial order will convince you of their utility

The Safe and Certain Boiler Cleanser

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.**

BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.

Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

Shell-Bar Boico Supply, Limited 1-15 Saunders Ave., Toronto

MACLEAN STOKERS

No Special Knowledge

is required to operate the **MacLean Underfeed Stoker.** It is very simple and **automatically** regulates the feed of fuel and air so that **complete combustion** is ensured. Apart from the great saving in labor, increased steaming capacity and improved conditions, it will fire your boilers on soft coal **without smoke.**

Let us estimate just what the MacLean Underfeed Stoker could save in your plant — no obligation.

The Coal it saves soon pays its cost.

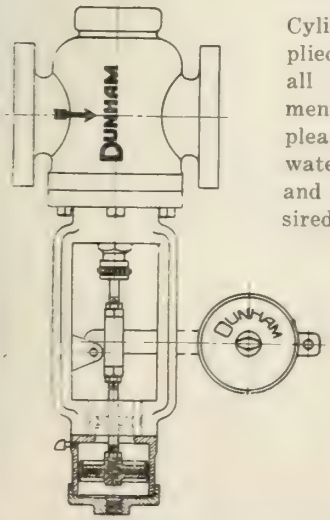
REDUCING PRESSURE VALVES

High Pressure Cylinder Type No. 305
Cross Section of Cylinder



Cylinders can be supplied in sizes to meet all pressure requirements. When ordering please specify steam, water or air service, and the pressures desired.

For High Pressure Reduction

70 to 300 Pounds or More

Where steam, water or air is to be reduced to pressures exceeding seventy pounds we recommend the installation of the Dunham High Pressure Cylinder Type Valve. Unlike the more commonly used Dunham Reducing Pressure Valves which are diaphragm equipped, this valve is constructed with a cylinder and piston specially designed for high pressure delivery service. It obtains constant pressure reduction and affords an adjustable variation of sixty pounds by means of weights.

Like all the products of the Dunham Line, this Reducing Pressure Valve embodies only the finest materials and expert workmanship, insuring dependable and lasting performance.

Write for additional data.

For Maximum Power Delivery Install "P M S" Belting

Two principal factors enter into maximum power delivery: efficient transmission and continuity.

"P M S" excels in both of these. By its greater adhesion to the pulley it gives a high percentage of efficiency. By its great strength it reduces breakdowns and adjustments to the minimum.

On this basis, we claim it is the best for your plant —will you test our claims?

Pressure Easily Regulated

THE two De Laval two-stage 8-inch centrifugal pumps designed for 1,440 g.p.m. each against a maximum head of 325 feet, shown in the photograph, are installed in the water works pumping plant of Orillia, Ont. They are driven by variable speed motors, by means of which the pressure upon the system can easily be varied. Upon each base plate is mounted a tachometer driven by belt from the motor coupling, also suction and pressure gages, so that the operator can at all times know the speed and the pressure developed, from which it is possible to determine approximately the amount of water being delivered. The characteristic curves obtained when the pump was subjected to the regulation shop test show the delivery at other speeds and pressures.

The same station also contains a De Laval two-stage pump driven by gasoline engine, to insure continuity of service under all circumstances.

De Laval centrifugal pumps are ideal for motor drive because of their low starting torque and high efficiency. The motor can be selected to develop its highest efficiency at the normal rated delivery, which is conducive to high average efficiency and to high power factor in induction motors.

Describe your pumping requirements, and our engineers will be glad to make suggestions. Ask for special publication B-100.

Steam is Money— Don't Waste It!

Condensation—the parasite—saps the life and energy of your steam. To let it remain in your pipe lines is equivalent to actual squandering of money.

Condensation is quickly and completely removed from your pipe lines by the

FISHER STEAM TRAP
(Type 33)

It is a positive-acting steam trap that gives your steam a clear track. Your steam courses through the pipes dry and hot to the very end of the system.

The Fisher Trap helps maintain even heat —it pays for itself in the coal it saves.

Its sturdy construction insures a long life of satisfactory service. It never leaks—Monel metal valve and seat practically eliminate wire drawing.

Sufficient water is left in the bottom of the bucket to insure a perfect water seal at all times.

The Fisher Trap is proving itself a true friend to engineers throughout the world.

Our book, "THE FISHER TRAP," was written for you. Write for it to-day.

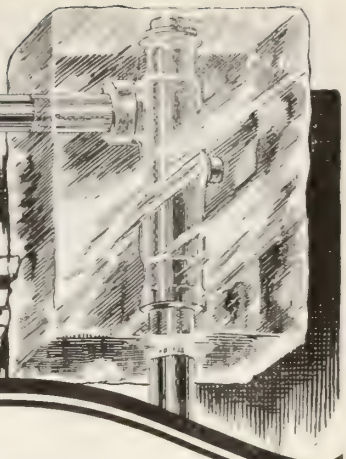
SARCO Trap Can't FREEZE



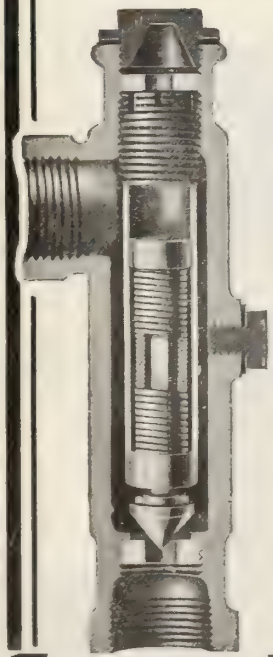
Even in zero weather the Steam Trap Sarco—when installed outside of a building—will not freeze or allow freezing of the steam line. It CAN'T freeze because it is opened by condensation and closed by steam.

When steam is shut off, the Sarco opens automatically and stays open until steam is again applied—then the steam forces all the air out and closes the trap until condensation opens it. No water stays in the trap or in the line.

This is a big advantage, for it enables you to place steam traps **at all points that ought to be trapped.**

All steam trap defects are overcome by the Sarco.

It drains all condensation as soon as formed. It doesn't leak—doesn't waste steam.



There is no steam hammer.

Is simple in operation. Has only one moving part—nothing to get out of order.

It needs no floor space or building up, and can be placed anywhere on the line at any angle.

And costs but one-third the price of bucket or float traps.

Made in sizes ⅜ in. to 3 in., for any given pressure up to 200 lbs.

Sold on 30 days' free trial. Booklet J-28 on request.

Exploding an Old-Time Boiler Fallacy

An Analysis of the Theory That Cold Water Sprayed Upon a Red-Hot Boiler Plate Instantly Generates an Uncontrollable Volume of Steam

By W. B. ROBERTS

IT IS the object of this article to thoroughly investigate and analyse a theory that appears to be gaining a strong foothold in this country, relative to the action of cold water upon a red-hot boiler plate. Those who care to investigate, will find that a very large percentage of engineers believe that cold water brought in contact with a red-hot boiler plate instantly creates a highly elastic vapour, which is so powerful and uncontrollable that no boiler would be strong enough to resist or withstand its effect. In some remote cases it has been advocated that explosions have occurred due to the ignition of hydrogen gas, produced by the decomposition of water coming in contact with the red-hot plates. We have only to look at a report issued in one of the daily papers on a boiler explosion that occurred this year in Canada, when we were informed—**"It is the general opinion of marine men who have inspected the boiler and wreckage, that cold water in the boiler was the cause of the disaster, but there is no official statement to confirm this report. The drawing of cold water into the boiler at a time when the crown sheet of the boiler was red-hot would have caused the blast, etc."**

We cannot close our eyes to the mischievous tendency that such a belief creates. Firstly, it diverts the attention from the true cause of the explosion, and secondly, it has a bad influence upon engineers who have charge of boilers. An engineer who accepts such a theory would naturally expect immediate disaster if he injected cold feed-water upon a red hot plate in his boiler. When we realize that self-preservation is one of the strongest instincts we possess, it is very natural that a man will not knowingly stand beside a boiler if he thinks it will burst.

It will therefore be readily seen that the acceptance of such a theory will not be conducive to the best results from any engineer, whereas, with a full knowledge of the whole truth, he could meet the situation of a red hot plate with the greatest equanimity.

With reference to the theory of "The generation of gas," we can dismiss this without further comment, and we think those who read this article will be well assured and satisfied that this does not actually occur. If, on the other hand those who give credence to "The rapid and instantaneous generation of steam" theory, would only consider the specific heat of iron compared with that of water, they would see that this theory is also doomed to disaster. The specific heat of iron (.113) compared with that of water (1.00) is so low that no large volume of steam could actually be generated under the circumstances. However, it is not our intention to prove the fallacy of such a theory by formula, but to prove from experiments actually conducted upon a boiler, that under such circumstances nothing unusual happens and there is nothing really mysterious about any boiler explosion.

We do not suggest that a plate in a boiler is not very materially weakened due to becoming over-heated. We know that bulges and bags on the plates of the furnace of a H.R.T. boiler are invariably caused by this condition, and it is possible and even probable that explosions have actually occurred due to this same cause. A boiler explosion is always caused by excessive pressure. It may be suggested that the plate of a boiler might be defective or wasted, but if the working pressure was determined to provide for such weakness or defect, the boiler would not explode.

Some years ago there was a regular epidemic of boiler explosions in Eng-

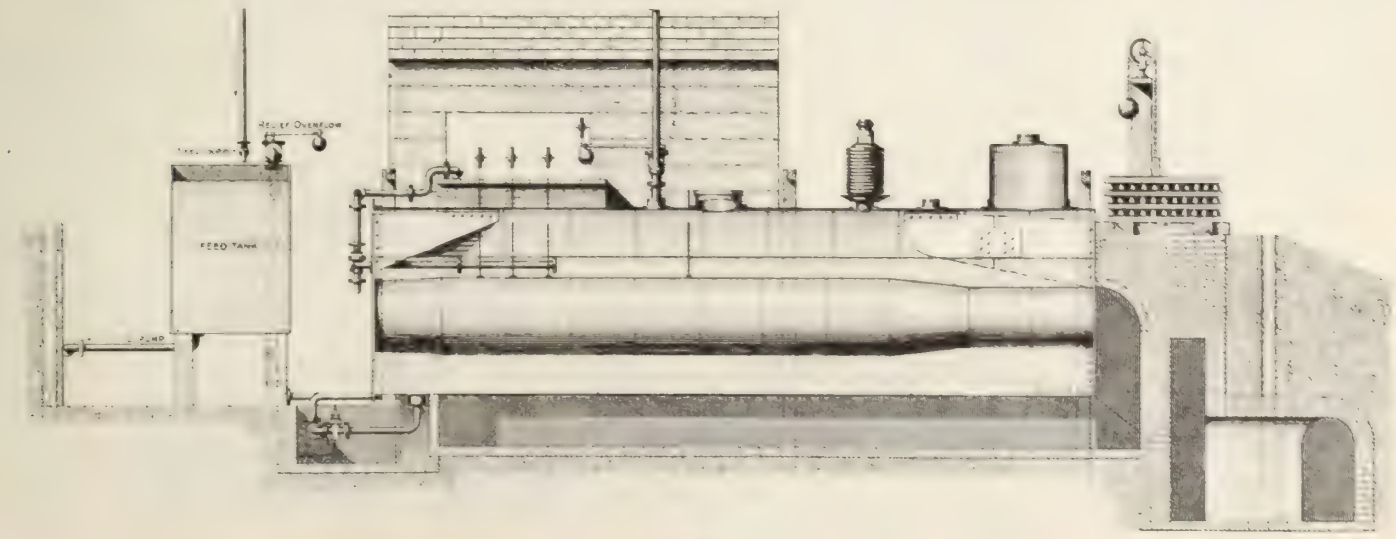

Fig. 1.

land. In many cases the cause for these disastrous happenings was said to be due to "A sudden and violent generation of steam" or "The explosion of a gas internally." However, whatever the cause the results were equally disastrous and it was thought that the time was opportune to thoroughly investigate the circumstances of such happenings and disprove any theory that savoured mystery.

At this time the Manchester Steam Users' Assn. undertook to conduct an experiment with a full size boiler, and after much reluctance on the part of the various authorities, to give their consent, it was eventually granted. Needless to say, such an experiment was greatly criticised and there were no few advisers who enlarged upon the dangers involved and predicted disaster.

A site was eventually secured on a piece of waste ground outside of Preston near to the boiler shop of Joseph Clayton. It was also necessary to take every precaution to protect observers, and persons in the vicinity outside the works. To effect this the boiler was set in a pit with large barricades built on either side and reinforced with earth. The observation pit was constructed some distance away and barricaded in a similar way to protect those conducting the experiment.

Selection of Boiler

It was decided that the boiler most suitable and adaptable for this experiment would be an ordinary Lancashire boiler and one was secured 7 ft. 0 in. diameter, 27 ft. 9 in. long, shell plates 7 16 in. thick, and plates 9/16 in. thick, furnace tubes 3 ft. 0 in. diam. and plates 7 16 in. thick. The boiler was set upon a proper standard brick setting and equipped with all the fittings necessary for a boiler of this type. Many additional fittings were essential to conduct the experiment successfully. An internal dispersion pipe was arranged directly over the furnace in the location of the plate that was to be over-heated and heavily perforated such that a uniform spray of cold water could be directed upon the hot plate at the required time.

These pipes were 7 ft. 0 in. long and extended from the front plates to the level of the bridge wall. The ends of the pipes were perforated on the bottom with about 35 ¼ in. holes, set 1¼ in. apart and in a position to direct the cold spray of water immediately on the red hot plate of the furnace. They were capable of discharging 5 to 6 cubic ft. of water per minute against a pressure of 25 lbs., which would be the pressure at which the boiler would operate. Fig. 2.

It was also necessary for the observers conducting the experiment to have some instrument or apparatus fitted in order that they could closely observe any movement, in the form of hogging or sagging, of the furnaces, and furthermore keep a close record of any distortion of the furnace in the form of bulging that would occur. To effect this, screwed plugs were fitted into the crown of the furnace equidistant over the length of the actual fire-grate.

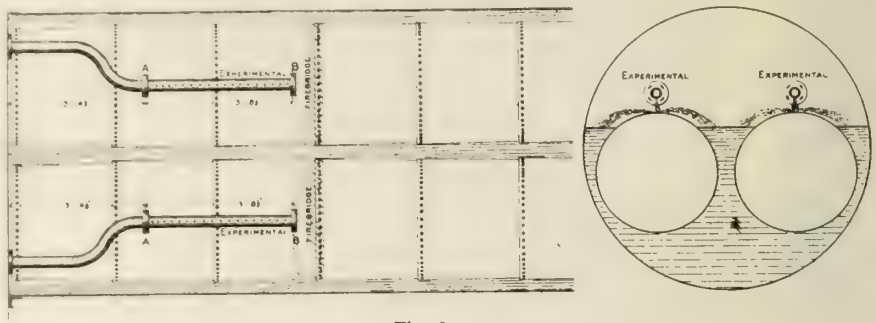

Fig. 2.

The screwed end was attached to the furnace with a disc of tin alloy to form a fusible plug. This alloy was specially prepared by a firm of analytical chemists so that the alloy would not melt at a lower temperature than the temperature of a red hot boiler plate. By having this arrangement we know immediately upon the release of one of the plugs that the plate is red hot. We might further add that tests were conducted on this alloy, on a plate similar to the arrangement in which they would be fitted in the furnace, and the alloy was not dislodged or melted until the plate was a blood red heat.

These plugs were attached to weighted rods and passed through glands at the top of the boiler shell. From these rods wires were led over pulleys to a recording board in the observation pit. See Fig. 1. It will be seen from the sketch that any up and down movement in the furnace crown will be immediately recorded on the observation board when complete records would be kept. The observation pit was also fitted with a blow-out tap in order that the water in the boiler could be lowered at the desired moment; a feed valve to regulate the cold spray on the red hot plates at the required time; extra glass water gauges to indicate the water level; a pressure gauge and a clock. A plan end and side elevation of the general arrangement is given in Figs. 1, 3, and 4.

With a view of saving time the water that was pumped into the boiler was first passed through an economizer in some of the tests, and the temperature of the water stood at an initial temp. of 150° F. We will, however, take the test where the boiler was filled up with cold water, as this will be conducting the test under more normal conditions. Although the boiler was built for 80 lbs., the safety valves during this test were only set for 25 lbs.

TEST

In preparation for this test the fires in the boiler were lighted and kept burning for two days so that the draught would be good and the brickwork warm. The experiment was commenced at 6 p. m. when there was 9½ in. of water above the level of the furnace crown, and the steam pressure gauge standing at zero. The fires were then shaken up.

At 6.30 there was 25 lbs. of steam showing and the safety valves began to blow. At the same time the blow-off tap was opened full bore, there being 9½ in. of water covering the crown of the furnaces.

At 6.38 p.m. the water level in the boiler had receded to the level of the furnace crown. The fires at this time being good and fierce, they were left in

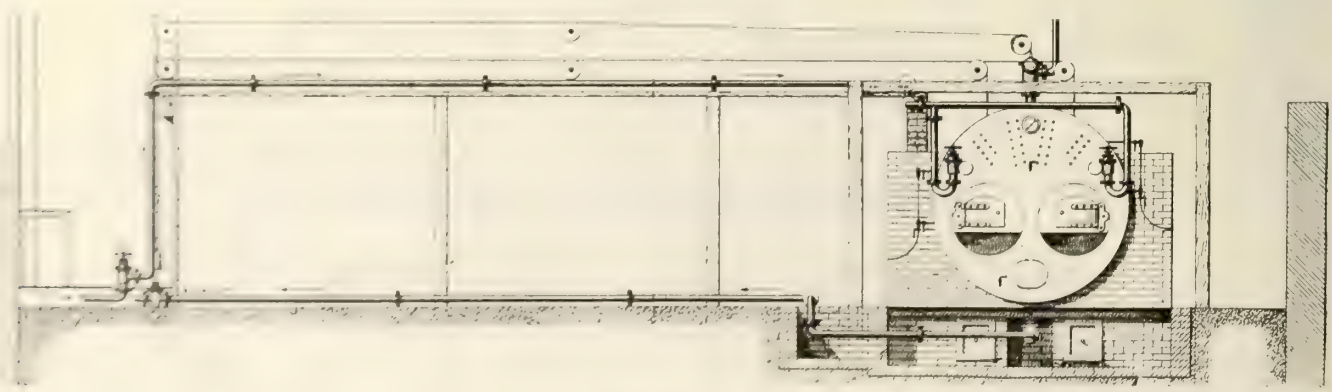

Fig. 3.

a condition wherein they would remain in that state as long as possible. The fires were 9 in. thick on the fire-bars burning briskly and the dampers were opened full, showing a draught in chimney of ½ inch on the gauge. The steam at this time was a few pounds in excess over 25 lbs. and the safety valves were blowing off violently. At this stage the observers withdrew from the boiler front to take records from their instruments in the observation pit.

At 6.56 p.m. and 18 minutes from the moment the furnace crown became exposed, one counterbalance weight fell on the observation board attached to the left furnace.

At 6.59 p.m., 21 minutes after the time the furnace crown became exposed, the falling of another counterbalance weight indicated that a second plug was dislodged from the alloy in the [illegible] hand furnace.

At 7-1½ p.m., 23½ minutes from the moment the furnace crown was first exposed, the third counter-balance weight dropped in the observation pit; this time from the right-hand furnace. At this moment the level of the water was 3⅝ in. below the crown of the furnace, thus laying bare and exposing a strip of plating 21 in. wide, at a temperature of about 700° F. with a pressure of 28½ lbs. of the boiler and the safety valve blowing freely. The feed water was immediately turned on, which would be conveyed through the dispersion pipe and sprayed directly on the red-hot plates. The temperature of the feed was about 60° F. and the rate of injection a little more than 4½ cubic feet of water per minute.

Showering the feed water at a temperature of 60° F. on a red-hot furnace crown was not attended with any increase of pressure. On the contrary the pressure at once began to fall and in 2½ minutes had fallen from 28½ lbs. to 26 lbs. pressure.

The rate at which the temperature rose and fell will be seen by reference to diagram in Fig. 5.

Upon looking into the furnaces the ring seams of the furnace tubes were leaking freely. The crown of both furnace tubes was discoloured on the fire side, for about 12 in. wide to a length of about 8 or 9 feet.

On making an examination of the boiler the following morning, it was found that the overlaps of the first seven ring seams in each furnace were sprung at the crown, but the shape of the furnace tubes was practically unaltered, except the right-hand tube was slightly bulged in three places. Two of these bulges were situated on the crown of the second belt, one measuring 7 in. x 12 in. x ¼ in. and the other 9 in. x 12 in. x 3/16 in.

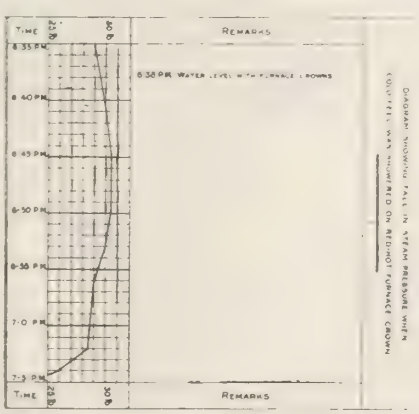

Fig. 5.

A third bulge was situated at the crown of the third ring seam measuring 11 in. x 10 in. x 5/32 in. deep. It was also seen that all the fusible discs on both furnace crowns had been melted. It would be just as well to here explain that the fusible plugs mentioned in this test are not the fusible discs usually used in ordinary boilers as there was no orifice running through them. They were simply fitted on the top of the furnace to indicate the temperature to which the furnace had been heated by the melting of the alloy.

In addition to the fusible discs and plugs a strip of lead 4 ft. x 1½ in. x 1/16 in. was laid across the middle of the first eight belts of plating of the furnaces as an indication how far along the furnaces the overheating would extend. It was found upon examination that five of the strips on the left-hand furnace and six on the right-hand furnace had been melted. There can therefore be no possible doubt that the furnace crowns had been red hot.

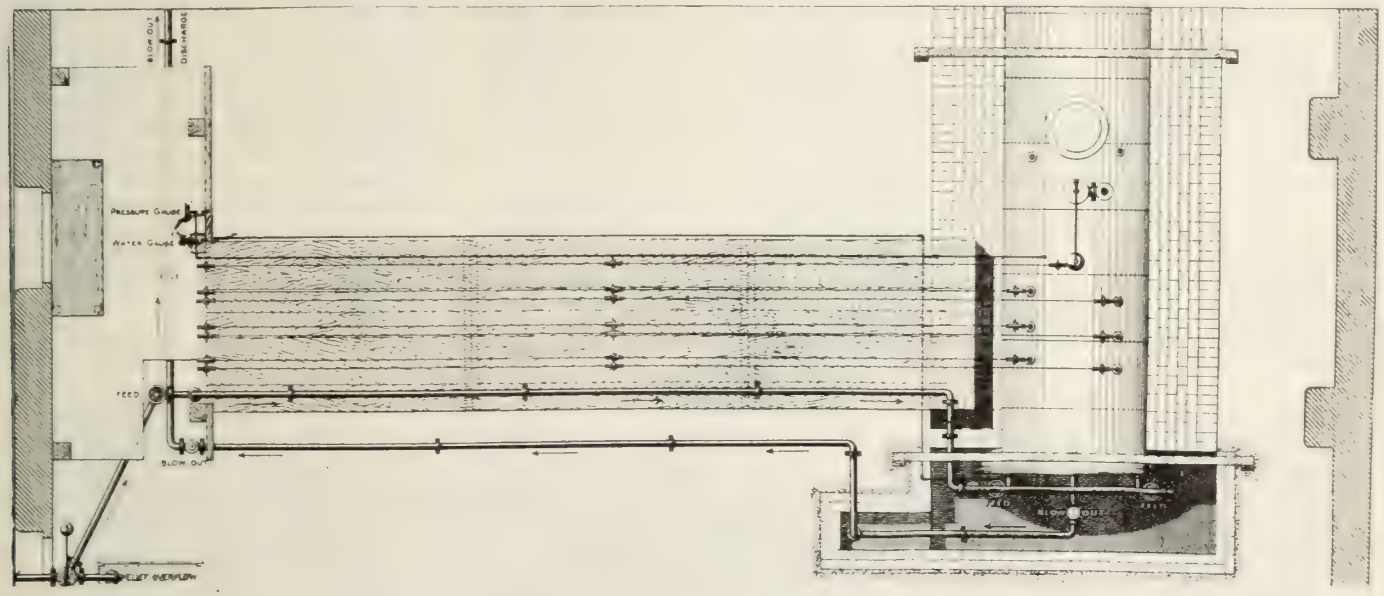

Fig. 4.

The results of these tests, which are plainly evident, clearly show that spraying red hot plates in furnaces did not lead to the ripping of the plates, circumferentially or longitudinally, due to sudden contraction or uneven expansion, and furthermore, did NOT CAUSE ANY INCREASE OF PRESSURE due to a violent and sudden generation of steam, but rather to the contrary SHOWED A SLIGHT REDUCTION in pressure.

The type of boiler that we have dealt with in these tests, is not one usually found in this country, although there are a few. However it was only used as a convenience to disprove the fallacy of a certain theory, and the results obtained are applicable to all boilers.

An attendant should never neglect his water supply, and if there is any doubt, he should make doubly sure of his water level before brightening up his fires. If these simple precautions were taken by everyone who look after boilers, even night-watchmen, there would be few cases of low water in a boiler, but if due to some unavoidable cause, the level of the water in the boiler is found to be low, do not hesitate in opening up your feed supply full and as a precautionary measure, draw your fires or at least dampen them down.

Pumping Engine Arrangements for Waterworks

The Development of Modern Pumping Machinery Showing the Most Economical Arrangement—Giving An Analysis of British Methods Compared With Those Used in America

MAJOR JOHNSTONE TAYLOR

Of all mechanical machines of what may be termed the heavy class, the modern waterworks pumping engine is perhaps the finest example. The slow engine, with its almost silent operation, must appeal to the unmechanical mind far above the ordinary run of machinery, whilst for reliability and efficiency there are few if any machines to compare with it. Despite the advance in the design and construction of the centrifugal pump and the undoubted convenience of the electric motor for driving it, the steam driven reciprocating engine still continues to hold the field where pumps are required for large water supplies. For smaller plants no doubt the centrifugal pump has several advantages, whilst the power-pump driven by gas or oil engine, has much to recommend it.

With this class of plant however, this article is not directly concerned, since it aims rather at discussing from a general standpoint the high duty steam driven waterworks engine. The continued adherence to the reciprocating steam engine, which for other purposes has been so much superceded by other forms of prime mover, is not far to seek.

The duty of waterworks pumping engines demands two essential qualifications, i.e., reliability and efficiency. No form of engine has yet been built which is more reliable than the slow speed steam engine and few can compare with it. Its efficiency when constructed, especially for economical operation, is exceptionally high.

These engines, certainly as far as British practice is concerned, are highly finished externally, having the cylinder lagging bonded with polished Russian iron. The external rods are all highly polished and the gauges and indicators grouped on a board at the front of the engine. The whole machine, when well cared for, has a most imposing appearance, and although appearance has nothing whatever to do with efficiency, a good one displays pride of work on the part of the builders, and is usually no mean indication of a good machine.

Types

There are two main types of water-

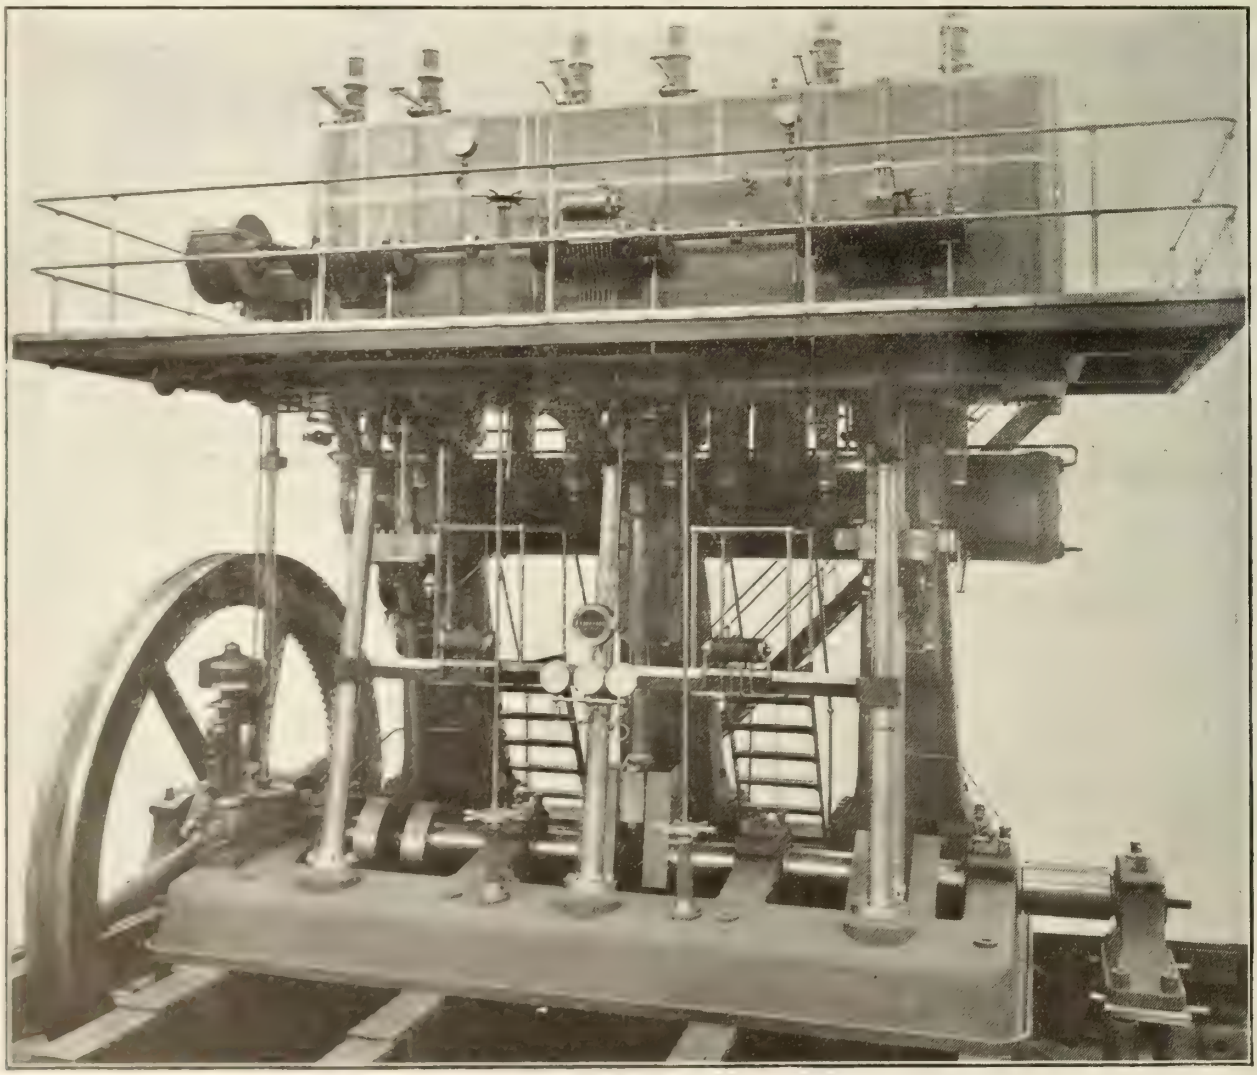

Fig. 1.

works engine now in use, the rotative and the non-rotative. The former as far as British practice is concerned generally takes the form of an inverted triple expansion steam engine driving three pumps direct from the crosshead. The engine is usually situated level with the engine room floor and the pumps with the condensing plant and other auxiliaries situated below it. This type of engine is also built in America, but the horizontal type, having the flywheel in between the steam cylinder and the pumps, is rather more popular in that country and receives little recognition in England. In a few isolated cases however, horizontal engines are found with the pumps behind the cylinders, the whole arrangement being much on the lines of the orthodox slow speed air compressor. There are, of course any amount of other practical arrangements such as vertical engines with horizontal pumps (the angle arrangement); pumps driven from an extension of the engine crankshaft; the rocking lever system, etc., all of which will be referred to.

The non-rotative pump, as its name implies, has no crank or flywheel. It is really a refinement of the duplex pump used for a variety of purposes. The ordinary duplex pump with plain slide valves and simple cylinders, is little used for waterworks duty. It is notoriously wasteful of steam, and compounding does not greatly improve matters. Some years ago, however, Worthington reconstructed this pump beyond all recognition, by the introduction of Corliss valves, compound and triple expansion cylinders, and other improvements, including the compensating device.

The Davey system of non-rotative pump has also been largely installed. It also has compound and triple expansion cylinders with a compensating device, but whereas the Worthington is a two-line engine, having two sets of compound or triple cylinders side by side, the Davey engine is a one line engine only. The latter is now losing favour for a variety of reasons, preference being given to the expansion rotative type by British engineers.

Fig. 2.

The non-rotative type, especially the Worthington engine, occupies less floor space than the rotative type, although the saving is not very marked. If well designed its efficiency is high, but it cannot be said to be as high as that of the best rotative engines of large size, and the mechanism is more complicated. Most of the recent engines installed have been of the latter type and there would appear to be, after all, little if any advantage to be shown by the non-rotative except in special cases.

The Steam Engine. Its General Arrangement in British Practice

The general arrangement of the steam side of a modern waterworks engine of the rotative type usually takes the form of three cylinders. These are mounted on the usual cast iron frame or columns and attached to a heavy bed plate all of which bear a close resemblance to the orthodox marine engine. The details, however, are usually not very different.

The slide valve or piston valve is not very often used on these, being almost invariably of the Corliss type although not necessarily so. Eccentric drive from the main shaft may serve to operate them, but a revolving gear driven way shaft is quite common. The Corliss valve is peculiarly adapted to this class of engine. Combined with steam jacketted cylinders, automatic cut-off, and high pressure superheated steam, the Corliss valve engine is capable of the maximum efficiency. Three cylinders are generally used, but there are cases where a compound engine would serve the purpose equally as well as a triple expansion and cost less to build. With compound cylinders the flywheel and pumps are usually arranged according to American practice. The vertical engine must have at least one flywheel, but sometimes there are two and even three. One of these may be toothed or racked for working in conjunction with a steam barring engine, or ordinary hand turning device. Governing is effected as a rule by the ordinary form of centrifugal governor acting on the cut-off of the h.p. valve, and which may be combined with some form of hydraulic governor. Surface condensers are invariably installed. It is usual to pump part or even the whole of the water raised through the condenser, doing away with a circulating pump and any necessity for cooling towers. The air pumps are usually worked off the main engine, although independent ones might be installed in special cases.

Failure of a public water supply would be absolutely disastrous to any large community, therefore the first essential is reliability. Efficiency from a coal consumption standpoint is of course most necessary seeing that water must be a cheap commodity, the cost of which falls on the community at large. It must also be remembered that these engines usually work continuously, and even the smallest waste in steam repre-

setting additional fuel consumption, may, over a period, amount to a considerable sum. Efficiency and reliability must be the first consideration in the choice of an engine, and the slow speed, triple expansion engine, of the type used for waterworks without doubt fulfills this requirement.

A good example of a modern triple expansion rotative waterworks engine is seen in Fig. 1, which is a photo of a Worthington Simpson engine operating at the Hong Kong waterworks and wherein drop valves are fitted throughout. It must not be inferred from what has been said that Corliss cylinders are quite universal in waterworks engines. As a matter of fact Worthington-Simpson build several class of engines with drop valves, these valves being located in the cylinder covers and operated from a revolving way shaft. Three engines of this class have been installed at the Hong Kong waterworks, Tytum-Tuk section. The drop-valve engine was developed along with the Corliss when engine builders were making every effort to reduce steam consumption. It was largely used on high class mill engines before the introduction of the steam turbine. It has the same advantage as the Corliss valve in enabling the cut-off to be actuated by a trip gear.

It is, in fact, quite a good system for slow speed engine work.

Fig. 2 shows the general arrangement of the type of engine under discussion together with the pumps and other details. Referring to the lettering:

An alternative arrangement of the ram and valves, etc., is shown in Fig. 2A, having the same reference lettering. This arrangement of engine and pumps is now usually employed for the larger engines, ram pumps of this kind of course serving to force water to any desirable height. Where conditions warrant it, the distance rods may be longer than that shown, enabling the pumps to be placed some distance below the engine. With ram pumps there is a limit to the length of the rods on account of them being in compression. If well pumps of the bucket type were driven direct from the crosshead, the rods could if necessary be of considerable length. It is more customary to find these pumps driven by rocking levers, the same engine often driving a set of ram pumps.

Both the engines shown represent the latest practice of two of the foremost British builders, combining well-lift and surface force pumps which are an ideal arrangement from several points of view, and are frequently met with. Of course there are a wide variety of conditions which may be considered as more suitable to the non-rotative pumping engine, while several other arrangements for rotative engines are in common use. There is a quadruple expansion engine of this class working in Cairo, the fourth cylinder being placed above the middle one. This engine was made by Simpson's and although it follows waterworks practice very closely it happens to be installed for lifting sewage.

The angle system mentioned before is seen at the Barnet Well station of the Barnet Water Company. The High and

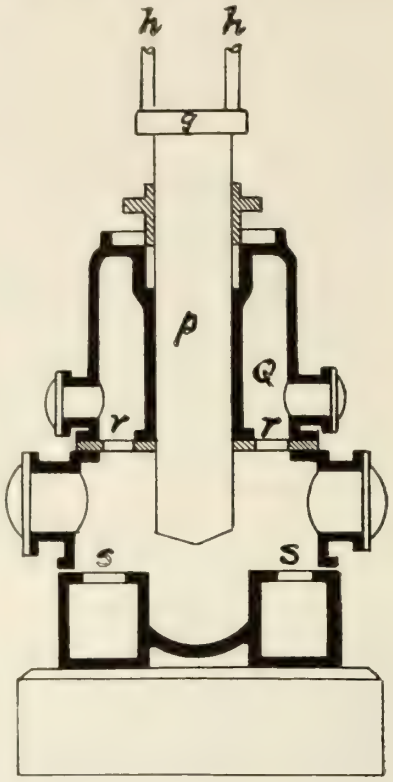

Fig. 2a.

Intermediate cylinders are vertical and the L. P. one is horizontal. There are two engines arranged over one well. Double bell-cranks are used to balance the work, also the long rods of the well-pump. Advantage is taken of this to arrange the cylinders and pumps so that the engine effort and pump resistance are directly distributed over all centres of the bell crank system in one plane, thereby ensuring great efficiency and steadiness in working. Corliss valves are employed and the pumps deliver 1½ million gallons in 24 hours to a height of 650 feet, of which 300 feet is from well to surface. At the Potters Bar Well, belonging to the same company, a horizontal tandem compound engine drives a double set of pumps also and raises half a million gallons to a height of 550 feet, of which 325 feet is well pumping. It is quite a small Corliss engine of under 100 h.p. but it gave a duty of 18 lbs. of steam per pump horse hour which is a good enough performance for a small engine.

The engine at the Broadmead Well of the Metropolitan Water Board is a good example of a pump where floor space is limited. The main pump, which is operated on the double bell-crank system consists of two working barrels. These are arranged in line vertically, one above the other and hang down the bore hole from the main engine frame by a column of welded steel tubes which are in lengths coupled together with externally screwed sockets. The two buckets are worked by wrought iron rods connected to crossheads driven from the bell-cranks, the top bucket having twin rods, and the lower bucket one rod. The centres of the bell-crank system are in this case wholly utilized for the various connections uniting the engine to the water end, including that of the flywheel, and the whole being self-contained on the main frames. This engine has one steam cylinder only. Several other examples could be mentioned. Even the old arrangement of beam engine built on modern lines, cannot be considered as entirely antiquated. An engine of this description is to be seen at the Chatham and Rochester Water Works. It is a compound rotative surface condensing beam-engine with high lift and delivers 3.3 million gallons per 24 hours, the combined lift being 380 feet. The high pressure and low pressure cylinders have Corliss valves, each independently driven from a central wrist plate actuated by eccentrics receiving motion from a countershaft. There is a governor-operated trip gear, the cylinders are steam jacketed, and the receiver is fitted with tubes supplied with steam direct from the boiler to act as a re-heater. Both sets of pumps are bucket and plunger pumps worked by separate connections from the crankshaft end of the beam.

(To Be Continued)

Babbitting a Loose Pulley

When a pulley is to be babbitted on a shaft and in the position it is to occupy when finished, and the tight pulley is already in place and known to run true, the loose pulley may easily be located by means of the other. When using an arbor, first secure in a perfectly upright position, put a collar on it that will form a support for the lower face of the pulley hub. After the pulley is placed on seal the joint with some suitable material as cardboard, felt or putty. Before placing the pulley on, it is well to cover the shaft with a layer of thin oiled paper, winding the same with heavy cord in a spiral form, the helix running toward the centre of the hub in the direction in which the pulley is to run. The grooves left in the babbitt after pouring will serve as ample oil channels and will likewise tend to keep the lubricant in the bearing instead of throwing it out at the ends. Should it be advisable to locate the shaft in a vertical position, the alternative would be to level the shaft horizontally and using a plum line across the sides of the pulley. By this method it is necessary to use a sealed collar on each end and it is also suggested to use a pouring hole in the hub instead of an oil hole, as the latter would afterwards require to be drilled out.

Efficient Lubrication of Air Compressor

Good Body Oil Required—Destructive Nature of Carbon Deposit —Affects the Proper Operation of Valves—Danger of Vapor Ignition—Cleaning Compressor and Piping System

SECOND only to the mechanical construction the efficiency of an air compressor depends on the systematic lubrication of the reciprocating and other movable parts which come in contact with the air being compressed. The purpose of lubrication is to reduce friction to the lowest possible degree and minimize the carbonization of the oil. The element of friction is probably the most serious as this is the primary reason for using the lubricant. The oil selected should have sufficient body to sustain the weight of the moving parts and form a film that will effectually prevent the piston rings coming in direct contact with the walls of the cylinder. On the other hand the oil should not be so heavy that excessive power is required to overcome the viscosity of the oil itself.

Carbon Deposit

The accumulation of carbon deposit resulting from the carbonization of the oil takes on a sticky condition when first attaching itself to the bearing surfaces but after a time becomes hard and flinty. This objectionable substance adheres to the cylinder passages, on the valves and in the pipe lines and air receiver. The inefficient operation of most compressors may be traced to the sticking or partial closing of the valves caused by the presence of this carbonized scale.

Other factors may be responsible for the accumulation of carbon deposit, but those generally found are:—the use of unsuitable oil, such as that used for steam engine cylinders, an oil that decomposes easily and quickly in the heat of the air cylinder; the use of too heavy an oil where the excessive viscosity prevents proper atomization, thus remaining too long in a liquid state on the hot walls of the cylinder and quickly forming into sticky deposits of carbon; too great a volume of oil, as too much good oil may have the same effect as a smaller quantity of heavier oil. The protection of the air intake is very important, as the entrance of dust, especially from coal, is detrimental to the proper operation of the compressor.

Fire Hazard

Apart from the objections just mentioned the presence of carbon deposit should be guarded against on account of the hazard that is associated with it. Particles of carbon may be torn loose and becoming incandescent might come in contact with the vaporized oil, given off by the lubricant, and igniting, the resultant fire being great or small dependent on the amount of carbon and vapor in the piping and receiver. Danger from this source can be practically eliminated by systematic cleaning of the carbon deposit.

As the temperature of compressor cylinders is governed more or less by the pressure of the air therein, the consistency of the lubricant used should conform to heat requirements. At the final stage of compression the air that has entered at atmospheric temperature has been raised from two to ten times; for instance, when maintaining a pressure of 10 lbs. gauge the compressed air when on the point of discharge from the cylinder will have a temperature of 145 deg. F., while the final temperature at 250 lbs. gauge pressure will be about 750 deg. F.

Rise in Temperature

The following table gives the temperature in degrees F. for air compressed to pressures of from 10 to 250 lbs. per sq. in. These temperatures are for single stage compressors—when using two-stage units the final temperatures will be approximately half of that recorded for single stage.

Air Compressed to	Final Temperature
10 lbs. gauge	145 deg. F.
20 lbs. gauge	207 deg. F.
30 lbs. gauge	255 deg. F.
40 lbs. gauge	302 deg. F.
50 lbs. gauge	339 deg. F.
60 lbs. gauge	375 deg. F.
70 lbs. gauge	405 deg. F.
80 lbs. gauge	432 deg. F.
90 lbs. gauge	459 deg. F.
100 lbs. gauge	485 deg. F.
110 lbs. gauge	507 deg. F.
120 lbs. gauge	529 deg. F.
130 lbs. gauge	550 deg. F.
140 lbs. gauge	570 deg. F.
150 lbs. gauge	589 deg. F.
200 lbs. gauge	672 deg. F.
250 lbs. gauge	749 deg. F.

The above temperatures are not to be taken as absolute, as variations from those given in the table will occur when air cylinders are water-jacketed and from radiation. Under good working conditions the higher temperatures given may be less in practice, while heat may be greater when machines are working at high speed on light pressure. Given temperatures are especially useful in testing oils to determine their resistance against the formation of carbon when raised to high temperatures. These given temperatures, however, are not to be taken as limits establishing the highest allowable flash point for an oil that may be used safely in lubricating air cylinders.

Mineral Oil Best

The most suitable oil for the specific purpose of air cylinder lubrication would be a pure mineral oil of high quality, free from any animal or vegetable oil mixture. The oil should be carefully filtered. Oils that have an asphaltic base are to be preferred over those produced from a paraffin base, as no matter how carefully the oils may be filtered, a small portion of carbon content will remain. Carbon deposited from asphaltic base oils is of a fluffy nature and may easily be removed from the cylinder wall and valve seats, while that deposited from paraffin oils soon takes on a hard, flinty appearance and is difficult to remove.

When using paraffin base lubricant on medium pressure machines the physical test should conform to that given in the table below:—

Gravity, Baume ..... 25 to 30 deg. F.
Flash Point (open cup) 400 to 425 deg. F
Fire ..... 450 to 475 deg. F.
Viscosity (Saybolt) at 100 deg. F. ..... 230 to 315 sec.
Color ..... Reddish
Congealing Point ..... 30 deg. F.

Oil having the above test figures is generally recommended unless a compressor manufacturer specifies that a high flash point lubricant should be used to meet the conditions peculiar to that particular machine. The possibility of carbon deposit is more likely from high flash point oil.

Asphaltic-Base Oil

For the selection of a suitable asphaltic-base lubricating oil the table below has been compiled. The figures given are for average working conditions.

Gravity, Baume ..... 19.8—21 deg. F.
Flash Point (open cup) 315—335 deg. F
Fire ..... 370—400 deg. F.
Viscosity (Saybolt) at 100 deg. F. ..... 275—325 sec.
Color ..... Pale Yellow
Congealing Point .....—0 deg. F.

When compressors are first installed they require a greater volume of oil owing to the character of the friction surfaces, but after the walls of the cylinder become smooth the quantity of oil may be reduced to avoid the possibility of carbon deposit. No more oil should be used than can be absorbed for adequate lubrication. Too much may be as destructive as too little.

A leading authority on compressor engineering contributes the following: "The best way to determine the proper amount of lubrication is to take out the valves from time to time and examine the cylinder. All parts should feel that there is oil thereon. If they feel dry, the lubricators should be adjusted to feed a little more oil, whereas if oil lies in the cylinder and its parts show ex-

The Commercial Economy of High Pressure and High Superheat in the Central Station

By GEO. A. ORROK
New York, N.Y.

IN this age of progress when the designers of central stations of all types and kinds are vying with each other in the use of higher pressures and complication of the steam generator, prime mover, and auxiliaries, it is expedient to go back to the beginnings of central station and by a review of the line of development to get a broad perspective of the field of power generation which will enable us to apply, to newer developments, those basic principles of commercial economy and efficiency necessary to a proper solution of the problem.

The earlier use of steam when its expansive force had not been discovered, is best shown by the Newcomen pumping installations, in which the steam was used at atmospheric pressure. Watt discovered the expansive force of steam and so improved the boiler, engine and steam piping that 15 pounds gage could be used economically. From his time until about 1900 rising pressure kept pace with improvements in materials and in the design and construction of steam generators and piping, with occasional excursions into the realms of higher pressure and temperature. Practice at this date (1900) may best be illustrated by the work of the Wildwood engine. Since 1900 improvements in steam generators, piping, and prime movers have been made with increasing rapidity, and many modern plants are running on 250 pounds and 200 degrees of superheat, using standard piping and valves with the newer designs of boilers, superheaters, and turbines. Table 1 shows the pressures and economies theoretically possible and attained in a central station, with all the results reduced to British thermal units in the coal per kilowatt hour of useful work.

TABLE 1—STEAM PRESSURES AND ECONOMIES THEORETICALLY POSSIBLE AND ACTUALLY ATTAINED IN CENTRAL STATIONS

Year	Engine	Pressure, lb. per sq. in.	Temperature, Deg. Fahr.	Thermal Efficiency, Carnot cyce per cent	Actual B.t.u. per kw-hr	Actual overall thermal efficiency per cent.
1700	Newcomen	15	212	2.7	416,000	0.82
1810	Watt	30	300	9.17	61,000	5.6
1900	Wildwood	215	400	20.8	19,200	17.75
1922	Modern	265	650	35.00	18.000	19.00

Our engineers are now using better and more uniform materials than ever before. Our metallurgical and manufacturing methods have been greatly improved. Copepr, wrought iron and cast iron have been discarded for boiler purposes. Steel and even alloy steel are in common use and their uniformity leaves little to be desired. Certain of the non-ferrous alloys are in common use and play their part in aiding the common security which characterizes modern installations. Copper boilers and 212 degrees maximum temparture gave place to wrought-iron boilers and 30 to 40 pounds pressure with a maximum temperature of 300 degrees. The use of steel as a boiler material raised the pressure to 200 pounds and the temperature to 400 degrees, while our modern steels allow pressures up to 400 pounds with a maximum temperature of 750 degrees. In certain distillation plants temperatures as high as 1,100 degrees have been obtained, but the life of the material is short.

Now it is well known that steel when heated to comparatively low temperatures, say, 900 or 1,000 degrees, loses its strength and becomes unfit to sustain loads, and the heat strains from even moderate heating of 300 or 400 degrees may cause certain deformations of a highly unsatisfactory character. Cast-steel valves have deformed at 750 degrees to such an extent as to render them useless, and the "growth" of ordinary cast iron at temperatures above 450 degrees is known to be destructive; but notwithstanding this the later constructions at 250-300 pounds pressure and 700 degrees maximum temperature are commercial. The first cost is not excessive, repairs are moderate, and the life of the installation is all that can be desired.

Commercial Limits of Pressure and Superheat in the Central Station

What, then, are the commercial limits of pressure and superheat in the central station? In Fig. 1 we have calculated and plotted the theoretical thermal efficiency of the Carnot cycle, the Rankine cycle, and a regenerative cycle, using both saturated and superheat values for ranges up to 1,200 pounds and superheats of 750 degrees and above. It will be seen that the chosen regenerative cycle for saturation follows very closely the efficiency of the Carnot cycle, while the Rankine cycle falls below the Carnot cycle increasingly with rise of pressures. The superheat lines for both cycles are nearly parallel and maintain this characteristic over a wide range. The gain from regeneration increases with pressure and is constant for equal superheat. For any final temperature the gain from pressure increments decreases, but gain from regeneration increases with pressure increments. Thus at 750 deg. final temperature the Rankine efficiency increases from 33.5 per cent. to 40.5 per cent. with pressure rise from 200 to 1,200 pounds,

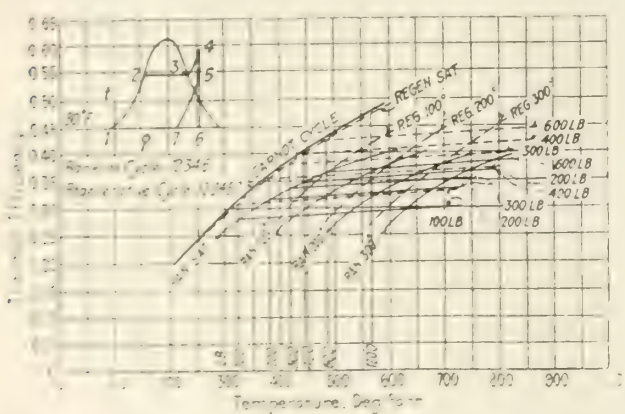

Fig. 1—Theoretical thermal efficiency of the Carnot & Rankine Cycle and a regenerative cycle using both saturated and superheat valves for ranges up to 1200 lb. and superheaters of 750 degrees and above.

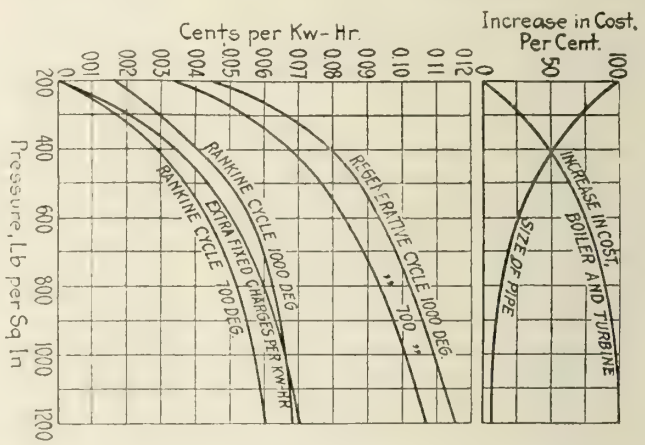

Cents per Kw-Hr.
Increase in Cost, Per Cent.
Pressure, Lb per Sq In
RANKINE CYCLE 1000 DEG.
RANKINE CYCLE 700 DEG.
REGENERATIVE CYCLE 1000 DEG.
" " 700 "
EXTRA FIXED CHARGES PER KW-HR
INCREASE IN COST, BOILER AND TURBINE
SIZE OF PIPE

Fig. 2—Saving in cents per kilowatt-hour for all conditions over the Rankine Cycle at 200 lb. and 700 Deg. maximum temperature based on $6.00 coal.

while the regenerative efficiency increases from 37 per cent. to 48.5 per cent. with the same pressure increase.

Fig. 1 dealing with theoretical efficiencies only, does not show the station losses which aggregate around 45 per cent. Grouping the losses, we may say that the generator efficiency is 97 per cent., turbine efficiency 78 per cent., boiler efficiency 80 per cent., leaving for auxiliaries, piping, and radiation 91 per cent., all of which multiplied together give 55 per cent. efficiency.

TABLE 2—SAVINGS EFFECTED THROUGH INCREASE IN STEAM PRESSURE.

Case	Cycle	Pressure lb.	Max. temp deg. Fahr.	Theoretical efficiency, per cent	Station efficiency, per cent	Actual efficiency, per cent.	B.t.u. per kw.-hr.
1	Rankine	200	750	33.5	55	18.4	18,500
2	Rankine	1200	750	40.5	55	22.3	15,300
	Saving			21.			3,200
3	Regenerative	200	750	37.	55	20.35	16,800
4	Regenerative	1200	750	48.5	55	26.7	12,800
	Saving			33.3			4,000

Table 2 shows how these figures work out for the above suppositions. The saving by regeneration when using 200 pounds pressure (Case 1—Case 3) is 1,700 B.t.u., and when using 1,200 pounds pressure (Case 2—Case 4) is 2,500 B.t.u. Considering the trend of the curves in Fig. 1, on this page, comparatively little is gained by further superheating, but there has been no attempt to go above 800 degrees, and the flattening out is much more marked as the temperature increases.

Water has its critical temperature at 704 degrees and the critical pressure is about 3,200 pounds. Pressures up to this limit may therefore be considered, and since oil-still temperatures up to 1,100 degrees have been used, we may consider superheat temperatures up to that point. We know that the first allotropic change in steel occurs at about 1,300 degrees, and 1,100 degrees is well below this point. Here, however, we must look into the physical properties of the steels used in power-plant construction.

When steel is heated the first sign of change—a dull red just visible in the dark—apepars at about 750 deg. Visibility in daylight begins at about 850 to 900 degrees and a full dark red is attained at about 1,100 degrees. The full cherry red is attained at the first allotropic change of 1,300 degrees. Good boiler steels increase in tensile strength up to about 600 to 700 degrees and lose much in ductility, but above 800 degrees the tensile strength rapidly falls off and the ductility largely increases. Cast steels of proper carbon content and suitable for fittings, valves, and turbine construction show the same properties within rather narrow limits. Pipe steels have nearly the same characteristics, but the temperature at which the tensile strength starts to fall is around 550 to 600 degrees. This lack of ductility or increase of brittleness at the maximum temperatures of use must be compensated for by a larger factor of safety (i.e., increased thickness and weight with higher cost) and a more careful selection of material. But with increased thickness it must not be forgotten that the safe stresses must be correspondingly lowered.

Variation of Strength of Materials with Temperature

This subject may be considered from five points of view, depending on the conditions under which the materials are to be used.

(a) Boiler Material.—Here we know that the maximum temperature cannot exceed 704 degrees, the critical temperature of water, and that the fire side of the tube or drum can only be a few degrees hotter. If 1,200 to 1,800 pounds per sq. in. be the chosen pressure the water temperatures is 625 degrees at maximum and the fire side will not exceed 725 degrees normally. This temperature is well within the maximum-strength zone, and only care is needed to secure sufficient ductility.

(b) Superheater Material.—The maximum temperature of the inner surface of the tubes may be a little higher than the maximum superheat. The outer temperature depends on the position in the boiler. Radiant-heat superheaters are now commercial where the pressure parts are protected with a heat-absorbing and conducting covering of cast iron. The fire surfaces may be 1,400 degrees to 1,600 degrees while the inner-wall temperature is as low as 700 degress, but 1,100 degrees is comparably easy of attainment. Bare-tube superheaters would have a maximum outside temperature of around 1,200 degrees, but the life at this temperature is unknown. The maximum safe point may be taken as 800 degrees superheat temperature and 950 degrees outside temperature.

Neither the tube manufacturers nor superheater manufacturers are afraid of these conditions, and I believe they are prepared to guarantee their product under such conditions.

(c) Piping Material.—Under this category the condition is markedly different. The steam side of the pipe is below the maximum temperature of the steam. The outer surface is much lower and the thickness of the material can be increased to compensate for the lower elastic limit of the material. The ductility is improving with temperature increase. Pipe joints are the only serious trouble, and the modified Van Stone joint with the pipe edges welded for tightness is the apparent solution. Experience with this joint has been satisfactory.

(d) Valves and Fittings.—Valves and fittings must necessarily be made of castings, and the low-carbon, openhearth steel used, while falling off in strength sooner than the worked material used in boiler and piping, has still a respectable elastic limit at 1,100 degrees. As in the last category, the inside wall temperature is lower than the steam temperature, with still lower temperatures at the outerwall. But the shape of the casting is all-important. Globe valves of the double-beat or Wanick type can be made with practically no flat surfaces and with two axes of symmetry. Internal pressures do not seriously deform this design, but external strains may cause minor troubles. Throttle valves and marine stop valves are usually of this type and can be kept tight at 750 degrees. It is probable that a temperature of 1,100 degrees could be safely undertaken with these valves if special precautions were used in the design of the seat, disk, and stem. Flexible-disk, double-beat valves are used in Europe at temperatures in excess of 750 degrees.

Gate valves have only one axis of symmetry and flat surfaces of considerable size. Here seat and disk troubles are encountered at temperatures above 700 degrees, and it may be some time before the manufacturers can guarantee a tight job at the higher temperatures. This type of valve is peculiarly sensitive to outside strains tending to deform the seats and disk.

(e) Turbine High-Pressure Ends.—Pressures can make little difference here as the high-pressure parts are comparatively small and without doubt the pressure will be reduced 50 per cent. in the first nozzle. There need be no high pressure stuffing box, so that the highest pressure to be packed against will be about half the maximum. Temperature strains will be the only thing that need be considered, and the expansion will reduce the superheat in the first-stage nozzle to a workable value, which is 750-850 degrees. It is to be noted that steam-chest or nozzle-box troubles have been the only prominent troubles where 400 pounds and 750 degrees superheat have been tried out, and it thus appears that a proper design will obviate most of the trouble. Cast or forged steel must be the material used.

In general, the turbine designers say that 1,200-1,500 pounds pressure has no terrors for them and can be used when desired. They can supply the apparatus. Temperatures are more troublesome and no one apparently cares to go much above 700-750 degrees at the present time. Superheater and valve materials at present seem to be the deciding factor in the use of high pressures and temperatures, and there is apparently very little which careful design and the selection of proper materials will not overcome.

Only a portion of the central-station installation is affected by high pressures and temperatures, especially where electric auxiliaries are used. The boiler and piping system and prime mover cover the entire list, and in the usual central station this has represented about 40

per cent. of the entire installation cost. Latterly, with the larger station the percentage is around 30, and may be taken at 25 per cent. for the newer and larger stations of which Hell Gate and Calumet are types. If the station cost be taken at $100 per kw. as an average figure this portion of the installation has cost $25, and at 15 per cent. the fixed charges are $3.75 per year or on 5,000 hours' use 0.07 cent per kw. hr. What, then, will be the extra cost of this apparatus when designed for higher pressures and temperatures? Standard boiler to-day can be bought up to 275 pounds pressure; 300 pounds necessitates thicker plates and tubes, and prices advance accordingly; 400-pound boilers have been purchased recently and 500-pound boilers have been built. Flash boilers of the Serpollet and De Laval types using pressures in excess of 1,200 pounds and coil boilers of the Herreshoff type using equally high pressures have been built as experiments or in toy sizes as for automobile work or for high-speed launches. Schmidt's water tube boiler working at 900 pounds has been run 14,000 hours with marked success. Boilers for 400-pounds pressure have been offered at about 50 per cent. increase in price and 1,200 pound boilers have been figured at a 100 per cent. increase in price.

Turbine designers are at work on designs arranged to utilize higher pressures, but higher temperatures seem more troublesome to them. I have no estimate, but we can safely apply the same percentage increases of price to the turbine that obtain with the boiler. Steam piping decreases in size with increasnig pressure so much so that it is doubtful if a 1,200-pound steam line would cost more than a 200-pound line of the same capacity. The volume of high-pressure steam at 1,100 degrees maximum temperature is quite uncertain, but the chances are that our figures are not more than 10 per cent. from the truth.

Summary

We may then summarize as follows:

a Pressures up to 1,200-1,500 pounds at least are commercial and may be attained without serious difficulty.

b Temperatures for the present are commercial up to 700-750 degrees, which should not be exceeded until our materials for valves and superheaters are improved. More extended experience is necessary before the range of 800 degrees and over is attempted in a commercial installation.

c With the completion of the Steam Table Research it will be possible to calculate accurately just where the possible limits of economy in pressure and temperatures may be located. At the present time the uncertainty of all values above 200-pounds pressure and 4,000 degrees Fahr. temperature render most of our calculations of only academic value.

d There still appears to be more economy in a closer study of operation and construction losses—resulting in improving the efficiency of central stations installed in accordance with the present accepted canons of design—than in the attempt to widely increase the temperature range of our heat cycles. While we may save 400 B.t.u. per kw.-hr. by using a regenerative cycle and increasing pressure and temperature, it should be possible to save nearly as much by a reduction to the lowest limits of the heat losses which we know exist in our present installations.

Savings of Regenerative Cycle

In Table 3 we have given for 700 and 1,000 degrees maximum temperature and for four pressures the theoretical efficiency of the three cycles used, the practical efficiency of the Rankine and regenerative cycles, and savings per kilowatt-hour for all conditions over the Rankine cycle at 200 pounds and 700 degrees maximum temperature in B.t.u. and pounds of coal of 13.800 B.t.u. content.

In Fig. 2 these savings are plotted in cents per kilowatt-hour on the basis of $6 coal, together with the extra-fixed-charges curve. At the top of the figure are two curves showing the percentage increase in cost of boiler and turbine and the decrease in size of pipe required for a given quantity of steam. It will be seen that the extra fixed charges are always greater than the coal saving for the Rankine cycle (ordinary operation) at 700 degrees maximum temperature, and that the additional gain for the 1,000 degrees maximum temperature barely exceeds the additional fixed charges. We cannot then expect much from increasing pressures and the ordinary methods of using steam. Increasing temperatures help to some extent, but not enough to be attractive, since the saving is nearly all used up by the additional fixed charges.

With the regenerative cycle the results are much better and useful savings are indicated, increasing considerably with pressure and slightly with temperature. It is evident that some such regenerative cycle must be used, but the rewards from increasing temperature are not commensurate with the costs. Many regenerative cycles are possible, but the one used shows nearly the maximum economy. Such cycles need many heat interchanges and a number of separate feed pumps for the close approach to theoretical figures. Indeed, Thurston and Stanwood, in 1899 pointed out that with an infinity of heaters and pumps the Carnot efficiency might be equaled. So far, however, four or five stages have been the ultimate practical application, and not more than three have stood the commercial test. It would appear that considerably better design must be put in the apparatus if many steps are proposed, and also that more consideration must be given to the operating difficulties.—"Steam."

LUBRICATION OF AIR COMPRESSORS

(Continued from Page 25)

cessive oil thereon, the quantity fed by the lubricators should be reduced. By thus examining the machine a few times, the proper amount of oil can be determined to suit the characteristics of the particular lubricant used and the conditions under which the machine operates."

Regular Cleaning

No matter how high the quality of the oil may be periodical cleaning should be consistently carried out to keep the walls free of carbon. Different methods are used to perform this duty but few, if any, will surpass the results obtained from the use of soap suds having the consistency of one part soft soap to fifteen of water. This mixture should be fed to the compressor through the oil inlet at about ten times the speed of the oil. This practice is advisable at least every two weeks, and during the process the air valves should be inspected to see the effect of the cleaning process and to act as a guide to the operator as to the quantity of solution to use. The machine should not be left after cleaning until it has been operating again for some time with the regular feeding of lubricating oil. This is necessary to prevent the possibility of corrosion.

The power plant of the New Brunswick Electric Power Commission at the Musquash river hydro electric development operations has been completed under the direction of C. O. Foss, chief engineer of the commission, and Dr. E. A. Smith, the chairman of the commission.

VALVE SEAT FINISHING TOOLS

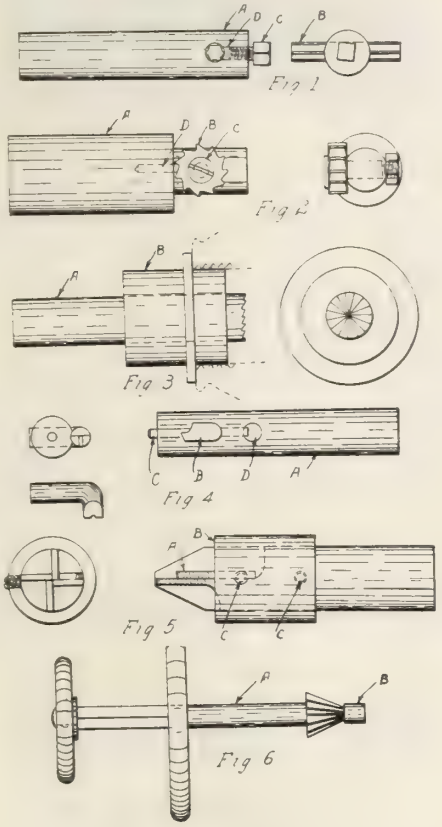
By Harry Moore

It requires two different tools, a rougher and finisher, to produce a good valve seat, although admittedly, very often, one tool only is used on this operation, the seats produced by the one tool method cannot be correctly termed good; at any rate not when the tool has been in use for any length of time. To state that a good valve seat must be smooth and uniform is to say something that everyone already knows, but the description of a few finishing tools designed to ensure this very necessary smoothness and uniformity will perhaps be of interest to many whose experience has not yet included this particular line of work. It should be understood the subject is herein treated as a manufacturing one, with particular reference to work of medium size.

Taking flat seats first, the principal troubles encountered are usually the difficulty of keeping the seats actually flat and the annoyances connected with chattering, which once started are so difficult to stop. A very effective flat seat finishing tool is shown in Fig. 1. The shank A is drilled through at one end to take the fluted tool B which is tightened in place by screw C bearing on the Vee pad D. The length of B is such as will allow it to enter the bonnet hole in the valve and the diameter of A is equal to the diameter of the valve seat hole and so pilots the tool when cutting. A perfectly flat, smooth seat is produced by this tool when properly made, and all six cutting edges can be used before regrinding is necessary, which, since the tool is only used for finishing and consequently does not have to remove much metal, is not very frequent. The flat seat tool shown in Fig. 2 is for use on what may be called exposed seats, that is, seats made on the surface of work—the bosses on machine castsings furnishing a good illustration of what is meant. The shank, A, may be made any convenient size, but the front end is, as before, made to enter the valve seat hole in order to steady the tool B which is a circular piece held on a screw C passing through the shank at right angles. A pin D, is driven into the shoulder of A to prevent the tool moving under the cut. The same advantage of several cutting faces is presented in this tool.

Fig. 3 shows a simple rectifying tool for reseating flat seats, which have, for this purpose, been returned for some reason or other. It is out of the question, of course, to rechuck such returned valves in the special chucking fixtures used on this kind of work, but with the aid of such a tool as shown a valve can be reseated in exact alignment. Part A is held in the chuck of a speed lathe, and B, which is a running fit on A, is gripped in one hand while the machine is running and the valve bonnet threaded opening pushed onto it up to the shoulder. A and B thus practically take the place of the valve stem and bonnet, and when the valve is pushed up against the cutting edge of the reseat will be exactly in line with the working parts.

A raised seat finished tool is shown in Fig. 4. This is used, together with a flat roughing tool, on brass castings. The flat rougher has a concave groove cut out on both sides of the cutting face, but the finishing tool has but one cutting edge as shown and better seats have been made than with a double edge



Valve-Seat Finishing Tools.

tool. The shank A is drilled at right angles for tool B which is made of drill rod bent as shown, the best cutting edge nesting in a shallow groove cut in the side of A. A pin C driven in the shank from the end holds the tool snugly in place and is driven out when required from hole D at the other end. By making up a dozen tools at a time they are produced at small cost; the shank A being hardened, is used as a jig for drilling the pin holes.

A common type of angular valve seat finishing tool is shown in Fig. 5; with an auxiliary tool for removing the objectionable burr thrown up by this in operation. As shown, one flute is milled further along than the rest and a flat piece of steel A is laid on the face and held in place by a collar B tightened by screws CC. A is adjusted in or out to slightly chamfer the top of the seat and being used only for this purpose can be kept with a very keen edge. In the last figure a hand finishing tool is shown for use in cases where the work cannot be brought to a machine. Although shown with an angular seating tool the same idea can be used of course on any shaped seat. The tool itself A, is squared on the shank for about half the distance and an ordinary valve wheel driven on to the end of square. A turned down portion on the end carries a smaller wheel, resting on a washer at one side and riveted over at the other, care being taken to leave the wheel a running fit. Different sizes of pilots B are used to take care of various sizes of valves and the tool is made to cut by turning the big wheel with one hand and applying pressure on the small wheel with the other. With proper fitting pilots this tool produces a well finished seat, very little pressure being required.

MOUNT ROYAL HOTEL IN JAN. 5TH POWER HOUSE

An outstanding feature of the Jan. 20th issue of Power House will be a carefully prepared detailed description of the power plant in connection with the new Mount Royal Hotel at Montreal. Descriptive details will be given with reference to the following items:

1. Methods of delivering coal at the hotel; weighing before placing in storage; handling and conveying to boiler room; coal hoppers, and the means whereby coal is weighed and distributed to stoker hoppers as required.

2. Steam generating equipment, including boilers, stokers, furnace linings and boiler fittings, also the ash hoppers, cars and hoist.

3. Pipe layout for distribution of steam and feed water system.

4. Boiler room auxiliaries, including boiler meters, gauges, feed-water pumps, heater and hot well tank supply.

5. Engine room steam electric generator outfits; also the motor generator sets.

6. Refrigerating engine and system.

7. Vacuum pumps and return taps; also air compressors.

8. Heating, direct and indirect; also the ventilating system.

9. Electric distribution system for illumination and power purposes, including the switchboard and instruments; also transformers.

10. Operating staff and maintenance.

This article should prove of unusual interest to all operating and designing engineers.

Steel work on the new office addition to be built on the the Montreal Tramways building on Craig St., Montreal, has been awarded to the Dominion Bridge Co. The structure will cost about $125,000.

Reviewing the Engineer's Position

IN TAKING over the editorial chair of Power House, I do so with a full realization of the responsibility I am assuming, on account of the very able manner in which this paper has been conducted in the past. This fact has been amply demonstrated to me during my short period of office by the number of congratulatory letters that we have received from our readers, expressing their appreciation of the subject matter that has been produced in its columns, and requesting a continuance of the same policy. One of the most notable of these, which is typical of the general feeling, is published under The Operators' Point of View in this issue, and which truly speaks for itself.

A letter such as this clearly demonstrates what can be done when a man has been inoculated with the "Interest" germ. The laborious daily work is converted into interest, and interest into enthusiasm. The boiler room is immediately transformed into a wonderful laboratory. Work loses its drudgery, and the process that you so oft have seen, becomes a beautiful experiment, with you, acting as the professor in charge.

It is when a man develops such an interest, that he has taken the first step towards success. Instead of working for his pay-cheque, he has something greater at stake. He is gaining an experience that will be invaluable to him later. With each experience, he is qualified to take a higher rung in the ladder of success, and so he slowly and surely ascends.

Unfortunately the war has had a destabilizing effect upon industry and labor throughout the world. Labor has been demanding and clamoring for the war-rate of pay, that it has long been accustomed to, and capital, on the other hand, striving for the higher percentage of interest. The situation is analogous to and can be fairly compared from a physics standpoint, i.e., action and reaction, and I think we can fairly say, that we are now nearing the end of the reaction stage. It is four years since the armistice was signed, and we can now naturally expect to see the situation assume a more normal aspect. The horizon is clearing and it will not be long before our factories are again humming and throbbing with life, and working again on full production. New extensions will be added and additional factories built. Then comes the time for reconstruction and it is to the engineer that all eyes will naturally turn.

It is the engineer that is the mainstay and the backbone of all industrial and commercial enterprises. Ask yourself where we would have been had it not been for the engineer during the war. Look back through the last century and see what the engineer has accomplished for civilization. Try and imagine into what chaos the world would be suddenly plunged if all the engineers were suddenly plucked from our midst, and it will give you a better idea of your position in the community.

When the time of reconstruction arrives, are you in a position to assume the responsibilities of the engineer in charge? If not, why? There will be quite a number of engineers who will suggest that they are lacking in experience. To them I would say, "Now is the time to get it." There are others who will suggest they have not had the university education. I remember a gentleman once defining to me the difference between the university and the self-taught engineer. He said, "One had learnt Latin and forgotten it and the other had never learnt Latin at all."

Now is the time to do the pioneer work, so that we will be in a state of preparedness to drop in on the big positions when they occur. Some of the ablest engineers I have met in this country have been self-taught men, and there is all the more credit due them for it. If there is perseverance and concentration of purpose behind a man's endeavor, the battle is three parts won, but, remember, education is the most essential requisite for all branches of engineering, and it is surprising what progress can be made by plodding.

It will therefore be my main endeavor to only include such subject matter in this paper that will be educational and instructive, to meet with the requirements of the power plant engineer. A number of educational series have been run through these columns in the past, which appear to have been highly appreciated. With a view to laying out my future programme, I would welcome any suggestion or constructive criticism that readers have to make, with a view to stimulating the interest in this paper, and, in so doing, I ask for your loyal co-operation and sympathetic support. I wish to contribute in helping to solve the problems that are ever confronting the engineer in his daily duties, and hope that my efforts will be made effective due to your sound directorship.

There are big opportunities ahead, and if you wish to be in a position wherein you can jump in when these occur, you must be prepared. Education is the only means of effecting this, and therefore my advice to all ambitious engineers, who wish to make any headway in their profession, is get the "Interest" bug.

The Season's Greetings

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

CHANGING ALTERNATOR

Question:—Would you kindly let me know through Power House if it is possible to change a 300 K.V. 2,200 volt. 2 phase generator into a 550 volt, 3 phase generator and how you would change the rotation of a 3 phase induction motor.—Huntsville.

Answer:—It is quite possible to change a 300 K. V. A. 2,200 volt, 2 phase alternator into 550 volt, 3 phase alternator.

The simplicity or not of effecting this change will depend on the type of winding at present on the alternator. Is it a rotating armature or rotating field type of machine, or is it a closed coil winding, or an open coil winding?

To obtain the precise layout of the proposed new arrangement of windings it will be necessary to know—number of slots on armature; number of coils per slot; number of poles, frequency and speed. With this information we can calculate the necessary phase displacement.

Let it be borne in mind that a 2 phase alternator is merely an alternator possessing TWO SINGLE PHASE windings, these separate windings being spaced 90 degrees apart. A 3 phase alternator possesses 3 single phase windings each 120 degrees apart, and simply one end of each of these 3 windings is connected together, either in star or delta formation.

It will be obvious that a winding that has given satisfaction on this 2,200 volts would also give satisfaction when working at a lower voltage In this particular case, we have to lower the voltage from 2,200 to 550. We shall therefore need to reduce the amount of the winding in the same proportion. Remember that a conductor has to cut 100,000,000 magnetic lines of force to generate 1 volt and seeing that none of the other factors, such as flux, speed, number of poles, etc., are to be changed, there only remains the number of conductors to be changed. If, however, we reduce the number of conductors, we will reduce the voltage generated, but if we desire the same amount of power as before, we shall have to increase the sectional area of the conductors to accommodate the extra amperage. This can be achieved by connecting the surplus number of conductors in parallel, until we have the necessary sectional area of copper required and taking great care that the means used to connect these coils in parallel are outside the densest part of the magnetic flux.

The reduction of voltage now having been accomplished, we still have to change the number of phases. If the alternator is one of the old style closed ring windings it is only necessary to divide this ring into three equal sections 120 degrees apart, and at that point carefully make a tapping, seeing this tapping makes contact with all the paralleled coils. Each of these tappings are then taken to their respective slip rings, of which there must be three. If, however, the winding is the more modern type, it will most likely be either lap winding or wave winding, and may be either a distributed or a concentrated winding. In such a case a great deal more care must be exercised in the phase displacement, as we need to take more care in the selecting of the coil pitch. In this case for 3 phase displacement, the total number of coil sides must be divisible by three, this being the number of phases. This results in a full pitch winding, as each coil will span the exact distance between the centers of the adjacent pole pieces. One end of each of the completed phase windings is brought to a common junction point, whilst the other ends of each phase are connected either to their respective slip rings, or to terminals on the alternator frame, according to whether the alternator is either a revolving armature or revolving field.

If such a method is chosen for connecting to a common point, it will be known as a star connected alternator.

Instead of connecting to a common point, however, these ends may be connected in mesh or what is more frequently termed delta.

Should this machine be star connected:

The voltage between any two collector rings equals voltage per phase multiplied by $\sqrt{3}$ or 1.732.

The current in each line equals the current in each phase winding.

Should this machine be Delta connected:

The voltage between any two collector rings equals the voltage per phase. The current in each line equals the current in each phase multiplied by $\sqrt{3}$ or 1.732.

The operation proposed, however, presents many technical difficulties, and should not be attempted unless considerable experience has already been acquired in a similar class of work.

To change the direction of rotation of a three phase induction motor, reverse any two of the wires connecting on to the motor terminals.

GEO. R. ARCHDEACON.

Dec. 13, 1922.

CLEANING CASTINGS

Question:—We would be pleased to have you advise us what pickling process would be best for removing sand and cleaning grey iron castings.—W. H. C., Montreal.

Answer:—One of the most common methods of removing sand from castings is to soak them over night in a solution of one part sulphuric acid (oil of vitriol) and 4 parts water. This is to be kept in a wooden vat, painted on the inside with white lead. If the solution is kept boiling by having steam pipes running through it, several batches can be pickled in a day. This solution is only good where the scale is soft enough to be penetrated by the acid, which attacks the surface of the iron, leaving the scale loose so that it can be washed or brushed off.

If the sand is burned right into the metal there is only one acid which will remove it. Hydrofluoric acid will eat sand, and if kept in a glass retainer, will dissolve the glass, but it will not attack iron, neither will it affect wood, so a wooden vat constitutes the entire equipment. If the castings are immersed for two or three hours in one part of hydrofluoric acid and ten parts of water, the metal will be freed from sand as well as the hard magnetic oxide (scale). This solution is equally as effective on forgings, and is by all means the best method known.

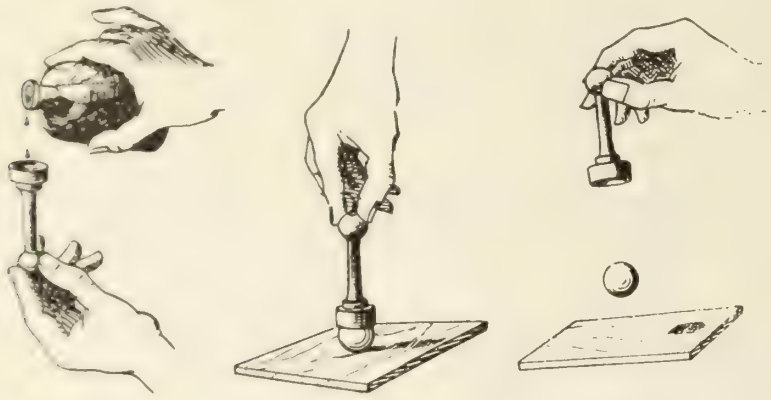
NEW BOOKS

Engine Room Chemistry, by Augustus H. Gill, S. B., Ph. D. Third Edition, 5 x 8 inches; 175 pages, published by the McGraw Hill Book Company, Inc., 370 Seventh Avenue, New York. The book is a comprehensive treatise on chemistry, dealing with combustion; the analysis of gas fuels, oils, feed-water and scale, and illustrated and explained in such a manner that it can be thoroughly understood by an engineer or boiler attendant. The 3rd edition is a revised treatise introducing a new chapter on combustion and bringing the book up to date.

Progress in New Equipment

THE MICHELL VISCOMETER

One of the most important tests determining the suitability of a lubricating oil for a given purpose is the viscosity test. The function of the oil in lubrication being to form a film between two surfaces sliding over one another and so prevent metallic contact, it is necessary to have a scale of measurement for viscosity, so that oil capable of forming this film may be obtained under any given conditions of temperature, pressure, speed, etc.



Hitherto the instruments employed have been of a kind suitable for laboratory use only; and, as most of them are based on the rate at which the oil runs through a capillary tube, the time occupied in testing, especially with a very viscous oil, is considerable.

This new instrument which we illustrate here measures viscosity on a new principle. The instrument consists of a cup of steel or cast iron having a perfect concave surface, and it is provided with a hollow stem or handle which forms a thermometer pocket extending into the metal of the cup. The surface of the cup has three minute projections, which prevent the steel ball from making complete contact and regulate the thickness of the film of fluid under test. To protect the concave surface from injury and to accommodate a surplus of the fluid, the cup is slightly recessed all around its edge.

In the workshop method of using the instrument two or three drops of the fluid to be tested are put into the cup so that when the ball is placed in position the gallery and annular recess are completely filled. The whole is then inverted and the ball and cup pressed firmly together on a clean board or pad to ensure contact between the ball and the projections on the cup. The method recommended by the makers is to rest the elbow on the bench whilst applying the full weight of the hand, i.e., 5 or 6 lb., on the knob of the instrument for a time, not less than half the time to the fall of the ball as determined by a trial reading. Pressure is then released for one second, and the Viscometer is raised an inch or so and held steadily in a vertical position. At the same time a stop-watch is started and the number of seconds from the lift to the fall of the ball is noted. The time in seconds divided by the constant of the instrument gives the viscosity of the fluid in dynes per sq. cm. at the temperature shown by the thermometer in the stem.

The principle of the action is briefly that the oil, by the preliminary pressure of the hand on the stem of the instrument, forms a film between cup and ball. On the pressure being released the oil film is no longer in equilibrium and a flow inwards is set up. The viscosity of the oil determines the rate of flow, and the rate of flow determines the time elapsing between the lift of the instrument and the fall of the ball.

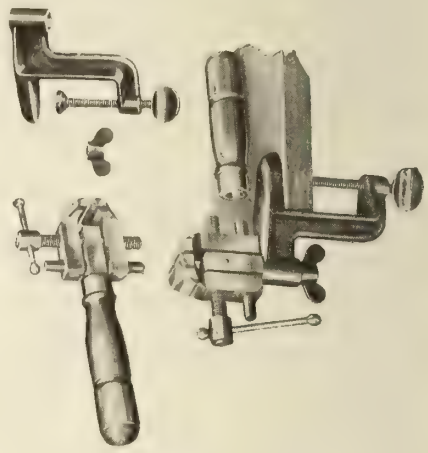
The viscosity thus obtained is the Absolute Viscosity, whereas with instruments of the capillary tube type the results have to be converted, by the solution of an equation, into Absolute units.

The method described above, whilst useful in classifying oils, is limited to the determination of their viscosities at atmospheric temperature. To find viscosities at different temperatures, the test with the Michell Viscometer is made with the instrument immersed in the fluid to be tested, the fluid having been raised or lowered to the desired temperature. This test is a laboratory test requiring more time and care than the method first described.

The constant given on the case of each instrument is that applying to the laboratory method of use, but this constant gives a degree of accuracy sufficient for use in the workshop test. The instrument is made by Michell Bearings, Ltd.

COMBINATION HAND VISE

A handy general utility combination hand vise has just been placed on the market. The use of a ball end handle for tightening the jaws instead of a wing nut is particularly worthy of note. By this means far more leverage is possible and thus a common difficulty in hand vises is eliminated. The hand vise is



furnished with a clamp permitting its use as a small bench vise on benches or shelves having an approximate thickness of ½ in. 2⅛ in.. As shown in the illustration the change is simply effected by removing the handle and substituting the clamp. When used with the clamp the vise can be adjusted to any point in a complete circle to meet the convenience of the user. The clamp is made purposely large and strong so that it will withstand hard use. The jaws are tempered and polished drop forgings 1½ in. in width. These tools are made by the L. S. Starrett Co., Athol. Mass.

Montreal—Boiler Equipment Company, Limited, are incorporated with $50,000 capital, to manufacture and market steam boilers, tanks and internal combustion engines, as well as contractors' equipment.

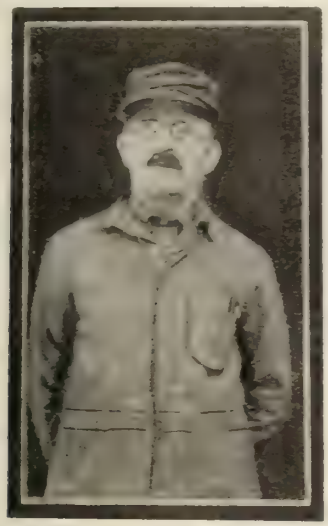
The Operators' Point of View

Acton, Ont. Dec. 4th, 1922.

Editor. "Power House," Toronto.

Dear Sir:—

I am glad to tell you personally that Power House has been, and is, a great help to me. It has made my work a pleasure and an interesting study instead of a coal shifting drudgery to be gone through each day, in a certain amount of misery, with long hours.



J. V. SAVAGE

What started me on the right road was your course of instruction for a higher grade certificate, published a little over two years ago. The first thing I learned, was the tensile strength of boiler plate, also the different riveted seams and the pitch of the rivets. Then came the difficulty of working out the formulas as I had forgotten all about fractions and sums. My interest was aroused and I was determined to go on, so I arranged with the Acton High School Principal to take me through the course, giving him $1 per hour for his help. After a few hours with him, everything became easy, and I cannot begin to tell you how thankful I am for what "Power House" has done for me. My work is now a pleasure, and whatever query my employer puts to me, I can answer him and prove my words in a technical as well as a practical way. I worked out two formulas in front of him last week in respect to an alteration in the plant I wanted to be made. Three years ago I could only have replied to his questions by gibberish and bull-shooting talk, and wonder afterwards if "It was a go," and wish I had thought to say something else instead.

Instead of burning three cars of coal last winter we only burned two, and since reading your articles published lately on combustion, I am on the road to better even that record.

I have no fault to find with "Power House" and as for ads, I think they are wonderfully instructive.

I hope you are not tired of this letter, but I am pleased to write to tell you how I appreciate your efforts for all stationary engineers and to my 60-year old self in particular.

J. V. Savage.

Mr. Savage first saw daylight in London, England, in 1863. At a very early age he became familiar with boilers and various equipment in a small factory owned by his father.

In 1913, however, he decided to seek his fortune in Canada, and after working with one or two concerns, he was in 1915 appointed engineer to his present company, Messrs. W. H. Storey & Son, glove manufacturers, Acton.

He is very proud of his plant, which consists of two boilers, a 25 H. P. single cylinder, non-condensing horizontal engine; one 15 H. P. gasoline engine; one 7½ H. P. motor and various other small equipment, all of which reflect in turn the master touch of a born engineer. He has a number of very ingenious contrivances about his plant, disclosing an original mind pregnant with ideas.

Mr. Savage is now studying for his 2nd Engineer's Certificate, and we trust through the medium of this paper, that we can be of still even greater assistance to him in enabling him to succeed in his new undertaking.

MACHINING PISTON RINGS

By John Magee

The majority of piston-ring manufacturers prefer to make rings with the finished surfaces ground to size. It is easier to hold accurate dimensions on a grinding machine than it is on a lathe. However, hard castings and hard spots in castings are machined without difficulty or detection by grinding. For this reason piston rings with a turned finish on the diameter dimension should be specified. Neither the scleroscope nor the Brinell hardness test will disclose hard spots in castings. A ground finish may cover up many hard spots or a hard scale. The production of a turned surface is a somewhat slower process for the manufacturer, but it guarantees a uniform soft wearing surface.

Flatness is very essential, since a serpentine condition will allow leakage around the back of the ring through the ring groove. If all of the internal stresses are not removed during the process of machining, the ring is apt to to warp sidewise. Therefore width dimensions should be inspected with a light gage instead of with a micrometer. With the ring lying on a perfectly flat surface, a side warp will cause it to register oversize. With measurements at intervals the two points of the micrometer might indicate a parallel width on a ring considerably warped.

The most common defect in the manufacture of piston rings is the elliptical ring, generally termed "out-of-round;" tolerance may vary according to the amount that the ring is likely to be worn in on the block. At best it is desirable to keep the variation within very low limits, say, 0.00025 in. to 0.00050 in. If the tolerance is expressed in light-gage terms it is much more simple for inspection, because the light gage is at present the most practical inspection device for locating out-of-round rings.

No accurate data are available for determining the poundage or wall pressure of piston rings to accomplish definite purposes. Actual experiments conducted at different times for different purposes seem to indicate that a poundage in excess of 4 lb. per sq. in. of bearing surface is needed to prevent collapse under pressure. Therefore a poundage of 5 lb. per sq. in. has commonly been specified for all purposes.

There seems to be a diversity of opinion as to the proper gas opening or expansion allowance. This is probably due to the difference in the estimated temperatures to which a piston ring is subjected. Using 0.0000056 per in. per deg. as the coefficient of expansion of cast iron, a minimum opening allowance for maximum expansion is obtained by multiplying this coefficient by the circumference of the ring.

A flattened strand wire rope seven miles long, without splice in either strand or rope, was recently produced at Birmingham, England. It is 4⅝ inches in diameter and weighs 73 tons. It was shipped in coils on specially prepared and connected railway trucks.

Practical Electricity for the Power Plant Engineer

By G. R. ARCHDEACON, A.M.I.E.E.

AS the last article was devoted to the general elementary laws governing the functioning of a dynamo, we may now proceed a little further with the consideration of the practical application of such laws.

As the loop of wire on the armature is rotated between the North and South pole of the dynamo, the magnetic lines of force are cut by this loop. When the loop is in such a position relative to the poles as to cut the maximum number of lines, so will the E. M. F. induced in the armature be a maximum value. Both before and after passing this critical position the E. M. F. will be reduced in value. We therefore have a condition wherein this is a constantly varying value, gradually increasing and decreasing.

There is, however, still another effect to consider. As the loop comes into the range of the magnetic lines of force from the north pole. the current induced into the loop will be in a certain direction, but when the loop comes into the range of the magnetic lines of force from the south pole, the current induced will flow in the opposite direction.

From this it will be seen that the direction of current flow is constantly alternating from one direction to another. This is known as an alternating current.

All dynamos and alternators generate an alternating current.

The only practical difference therefore between the alternating current machine and the direct current machine, is simply the effect of connecting a commutator to the armature winding.

The function of the commutator, therefore, is to pick up the current just at the moment it is about to reverse its direction.

The brushes resting on the surface of the commutator convey the current to the external circuit.

The main parts of a dynamo are:—

FIELD MAGNETS to provide a magnetic field.

ARMATURE to provide the E. M. F.

COMMUTATOR to provide a collecting surface for the current flowing round the armature.

BRUSHES.—To collect the current from the commutator.

FRAME to provide support for the magnet poles, and for the bearings.

FIELD MAGNETS.—In all commercial dynamos the field magnets are made up of electro-magnets, and not permanent magnets, formerly these following the conventional shape of a "horse-shoe magnet," with the winding located round the centre point. This is all ancient history now, as all modern machines, are what is termed multi-polar, and consist of numbers of pole pieces, such as 4, 6, 8, 10, 12, but always a multiple of 2.

These pole pieces are evenly spaced round the yoke or frame of the machine. These pole pieces are known as cores, upon which is wound the field winding.

In choosing the materials for these cores it is necessary to bear in mind the permeability of the metal chosen, cast iron, cast steel or wrought iron may be used.

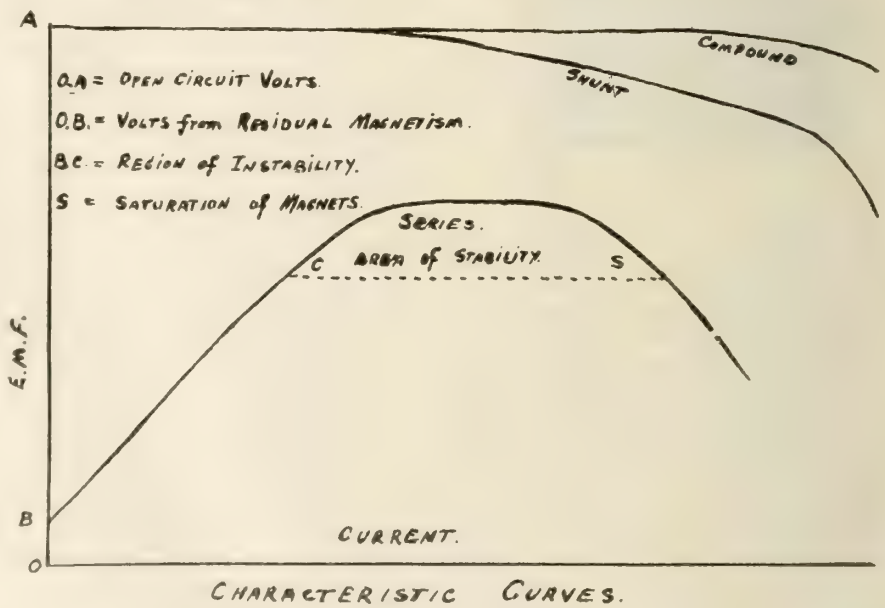
Wrought iron is most desirable, as it requires the smallest amount of material for a given magnetic flux. There is also a saving in copper due to using wrought iron, on account of its small size, the length of each turn of magnetising coil is reduced.

Cast iron is used because its cross section may be increased.

Cast steel appears to be intermediate between cast iron and wrought iron, but from the consideration of reluctance or magnetic resistance, wrought iron is the best material to employ.

For convenience in taking out the armature it is usual to divide the yoke into halves, the top half being provided with a strong eye-bolt, to permit of it being lifted up whenever necessary.

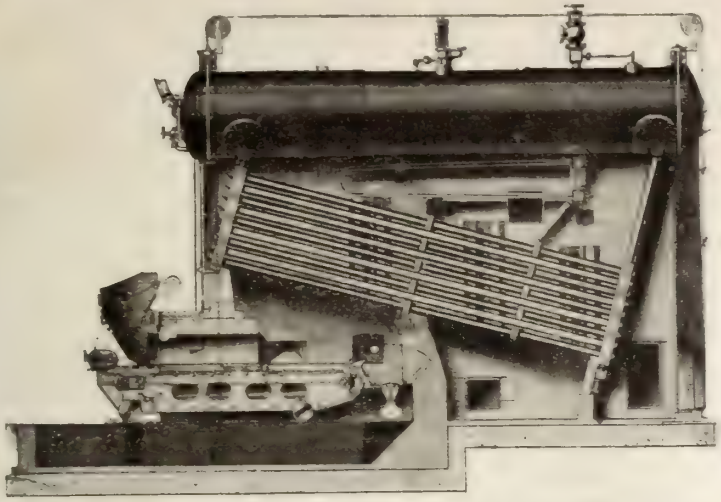
Unfortunately, however, this always results in an increase in the magnet resistance of the magnet circuit through the yoke, as no amount of careful fitting of the surfaces of the joint will make the connection as intimate as a solid mass.



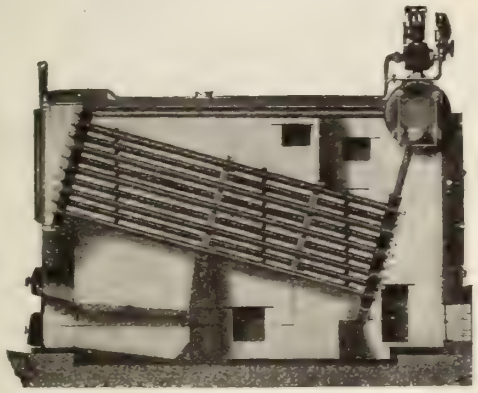
CHARACTERISTIC CURVES.

Any increase in the magnetic resistance results in a corresponding decrease in the magnetic strength of the pole, and needs to be compensated by the addition of several extra turns of wire in the field winding.

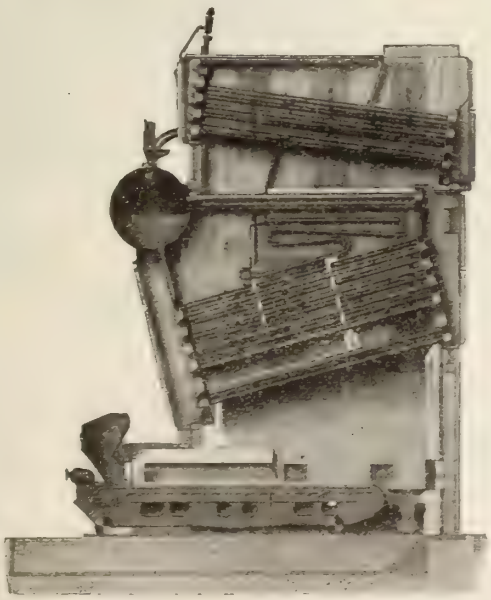
It will, therefore, be readily seen that should the permeability of the magnetic circuit be lowered, either through ill-chosen material, or bad contact in as-



W. I. F. TYPE—With chain grate stoker and superheater suitable for most purposes on land.



CROSS-TYPE—A most desirable form of boiler where headroom is limited.



MARINE TYPE—(For land purposes). The marine-type boiler is equally adapted for installation on Land and is especially suitable for electric generating stations and other quick steaming plants. Where ground space is limited, and expensive, it offers particular advantages.

EFFICIENCY DURABILITY SAFETY

THERE IS A TYPE

OF

B. & W. BOILER

TO SUIT EVERY CONDITION ALL HAVING THE SAME PRINCIPLES OF CONSTRUCTION, VIZ:—

Water divided into sections, no general explosion can occur.

Every section able to contract and expand without interfering with any other part of boiler.

Boiler as a unit can move without disturbing setting.

Positive circulation of the water keeps all parts at nearly uniform temperature.

Proper workmanship.

Materials which experience has shown to be the best for the particular purpose.

A great excess of strength over legitimate strain.

No joints or cast metal exposed to the direct action of the fire.

Perfect circulation of both water and gases. Proper proportions for work to be done at any rating.

Ample water and steam capacity and water space for disengagement of steam.

Scale forming materials and soot can be removed while boiler is working.

All parts readily accessible for cleaning and repairs.

Adaptable to any furnace burning any fuel, solid, liquid or gaseous.

No restrictions to draft.

QUICK STEAMING.

BABCOCK & WILCOX

LIMITED

ST. HENRY, MONTREAL

Toronto Office: Bank of Hamilton Bldg.

sembling that circuit, a greater number of ampere-turns will be necessary to obtain the required flux from the magnet, seeing that—

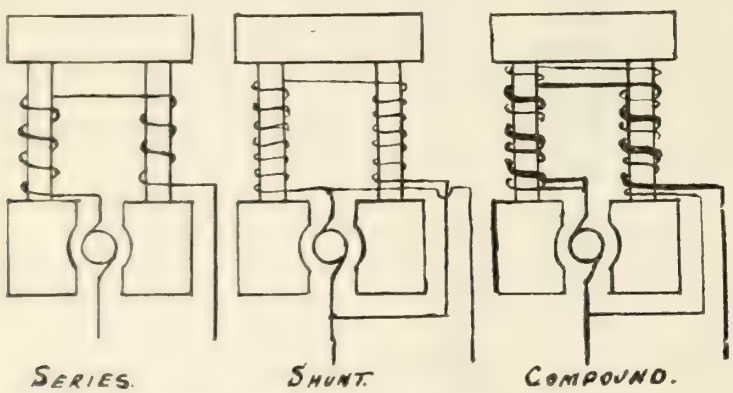
$$\text{Flux} = \frac{\text{Magneto-motive Force}}{\text{Reluctance}}$$

$$\text{Magneto-motive Force} = \text{Strength of Current} \times \text{Turns of Wire} \times 4\pi$$

$$\text{Reluctance} = \frac{\text{Length of Magnetic Circuit}}{\text{Area} \times \text{Permeability}}$$

$$\text{Ampere Turns to Produce One Line of Flux} = \frac{\text{Length of Magnetic Circuit}}{\text{Area} \times \text{Permeability}} \times .3132$$

The winding of the field coils is a comparatively simple matter, but care must be taken to see that the winding is in such a direction that it makes the pole pieces alternate north and south. To obtain this effect the winding on one pole piece will start at the face end of the pole, and terminate at the frame end of the pole, but the adjacent pole piece will have its winding starting at the frame end of the pole piece, and ending at the face end of the pole piece. By so doing the current will be flowing in opposite directions round each alternate pole, thereby changing the polarity of such poles.



FIELD WINDINGS.—There are three distinct forms of field windings.

(a) Series winding.

(b) Shunt winding.

(c) Compound winding.

Series winding, is a winding through which the total current supplied to the external circuit must pass, as this winding is in series with the armature. The coils must, therefore, be wound with wire of sufficient sectional area to carry the maximum current of the dynamo without over-heating, whilst at the same time it must also have the lowest possible resistance, otherwise there will be a serious drop in voltage.

Shunt winding is a winding through which only a fraction of the total current flowing in the armature is permitted to pass. The shunt winding being another circuit in parallel to the armature circuit, and of considerable higher resistance than the resistance of the armature.

Compound winding is a winding consisting of a series winding, and also a shunt winding on the same pole piece. The series winding consisting of only a few turns of wire of large sectional area, whilst the shunt winding consists of a great number of turns of wire of small sectional area. By correctly proportioning these two types of windings the machine can be designed to render satisfactory service under almost all conditions of load, and to be within certain limits automatically self adjusting.

Each of the above types of windings possess their own special characteristics, which may be briefly described as follows:

When the load on a series wound dynamo is small, the current flowing in the external circuit is of a low value. As this current must flow round the field winding, the degree of magnetisation of the field must of necessity be small, but when the load on the dynamo is great, a considerable amount of current is flowing round the field winding and on into the external circuit. Such an increase in current in the field circuit results in the increase in magnetisation, with a consequent increase in voltage.

From this fact is will be readily observed that in the case of a series wound dynamo, the voltage increases as the load on the dynamo increases, and decreases as the load is decreased.

This phenomena is more interesting than useful, as a steady voltage is the thing most desired. Just consider for a moment the effect of a voltage constantly fluctuating as the load varies; any such variation would render a lighting system most unsuitable to our surroundings, and certainly most irritating to our nerves.

When we consider the case of the shunt wound dynamo we find a different set of circumstances.

The shunt winding forming an independent circuit from the external circuit. Being in parallel to the armature circuit, only that fraction of the armature current may pass along it as its resistance will permit, and as this resistance is a constant value, the current passing round the shunt winding is constant within a very small limit of variation. Naturally the magnetisation is practically constant, and as a result the voltage of the dynamo is constant within such limits. Voltage fluctuations are therefore much less noticeable in the case of a shunt wound dynamo, than with the series wound type.

It must be borne in mind, however, that we arrive at a point when no additional amount of magnetising current will increase the magnetic flux of the pole pieces, as they will have arrived at a condition of saturation. After this point is reached the conditions become stable and the voltage of both series and shunt wound dynamos rapidly decreases, whilst the energy used in continuing to magnetise the pole pieces after this point is reached, is just so much lost power.

By compounding the windings, the shunt part of the compound winding will neutralize the series part of the compound winding, and in this manner it is possible to so proportion the windings that we obtain the average effect due to both the windings, and so can obtain a steady voltage under almost all conditions of load.

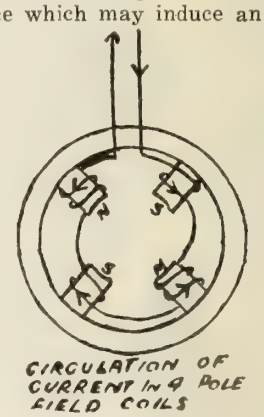
The winding of field coils is a much simpler operation than the winding of the armature, consequently whenever a fault occurs in this winding it frequently happens that the job of re-winding is given to the "handy man" around the plant.

There is one very important precaution which should be taken, which if neglected, serious damage may result to the machine, or possibly the operator of the machine.

It may so happen that the inner or starting end of the coil is brought out at the top of the coil. Let us just pause and see just what this means.

In bringing this end to the top, it must of necessity pass over a number of wires, forming the layers of wires in the coils that wind round the pole piece.

When current is flowing in this lead, there will be a certain amount of induction between it and the adjacent layers of wires, hence we are getting back to the condition required by Faraday in his early experiments on induction. When we interrupt this current flow we immediately develop a very high inductance which may induce an E. M. F.



of several hundred volts. The sudden collapse of the magnetic lines cuts the large number of conductors contained in the coil, with the consequent generation of a high voltage. It is for such a reason that an operator may receive a severe shock if this point is not appreciated by our "handy man." Unless therefore a considerable reinforcement

PRACTICAL ELECTRICITY

(Continued from page 36)

of the insulation on this particular lead is effected, this high E. M. F. due to the inductance of this circuit will in time be certain to puncture the insulation, short circuiting the coils, reducing your magnetic field, resulting in drop of voltage on the machine, perhaps causing a fire, and in case of a shunt wound motor, probably cause it to race at a speed which may cause it to burst, resulting in wreckage to the adjacent machinery, with possible loss of life to the operators in that section of the factory.

As a kingdom was lost for the want of a horse-shoe nail, so may the above dire results accrue for the want of a little extra care over a job that is too simple to devote a little thought to.

Many dynamos are now built with smaller pole pieces inter-spaced between the regular pole pieces and these are known as inter poles, or commutating poles.

COMMUTATING POLES.—Commutating poles are not intended to actually give additional power to the dynamo; their function is really to increase the efficient distribution of the magnet flux. This flux becomes distorted, which is why the brushes on the commutator are not located in the exact centre point between the pole pieces (this point will be treated in greater detail in a subsequent article). By overcoming this distortion of the flux, the tendency to sparking at the brushes is eliminated.

These commutating poles carry a winding which is traversed by either the whole of the armature current, or only a fraction of it, as pre-determined by the designer. All such poles are much smaller in area than the main exciting poles, as they are merely for corrective purposes, and not for the actual generation of the main energy of the dynamo.

Before the advent of commutator poles the output of a dynamo was strictly limited to its sparkless condition. We now can disregard such a limit, as sparking has been eliminated by correct proportioning of the commutator poles and we are therefore only limited by the temperature rise. With ample ventilation, a high speed dynamo may be running at a current density of over 3,00 amps. per sq. in., yet be entirely free from sparking at the commutator.

The addition of commutator poles to a dynamo results in a considerable increase in the capital cost, but when considered in the light of ultimate economy it would appear to be a desirable form of investment, and providing the machine possesses ample ventilation, a greater amount of energy may be taken out of the machine.

According to Mr. Hobart, the great designer of electrical machinery, he says: "In case of 250-volt dynamos, the ordinary type of construction is cheaper for all outputs so long as the speed does not exceed [illegible] revolutions per minute; at 200 revolutions per minute, the commutator pole design is desirable for 600 kilowatts, whilst at 1,000 revolutions per minute, it is desirable beyond 250 kilowatts."

From Mr. Hobart's conclusions it is apparent he takes advantage of the higher speeds to give an improved natural ventilation, irrespective of considering the particular design. From this we can accept a general law controlling operating conditions.

Any dynamo may be safely overloaded within its safe temperature limits, and the higher the speed of the dynamo, the greater percentage of the permissible overload.

VALVE GRINDING MACHINE

A portable machine for grinding automotive poppet valves to a definite angularity and for grinding reseating cutters used for facing valve seats to the same angularity as the valve has been developed and offered to the trade recently. The machine is not of the adjustable type as it is assembled at the factory to grind at a pre-determined angle, and is therefore a single-purpose tool. The machine is driven by a Westinghouse motor which is mounted on a low, flat base. It is so located on the stand that vibration is reduced to a minimum, so that accuracy of grinding is not affected. Movement of the valve holding spindle is obtained by means of a hand lever. Feed is by a small hand wheel and screw. These tools are made by the Franklin Machine and Tool Co., Springfield, Mass.

A BUSINESS EVOLUTION

Forty publishers of morning newspapers met in Chicago a couple of weeks ago and formed an association to promote the morning newspapers' interests in competition with the evening newspaper as an advertising medium. The chief method by which they say they intend to accomplish this is through announcements in the business newspapers of the United States—that is papers of the type of Power House.

This is an interesting evolution—the recognition of the place and power of the specialized newspaper.

Montreal.—P. Ackerman, electrical engineer of the Shawinigan Water & Power Co., has perfected an invention that has to do with relay protection making long-distance transmission of high electric power safer and more effective. Much interference with service was caused by lightning, wind or sleet storms. By the new method, a faulty section is disconnected automatically. Long distance transmission has been made safer and more effective.

E. B. Eddy Co., Hull, Que., are considering the location of a branch factory at Sault Ste. Marie, Ont.

A GLUE POT WITH AUTOMATIC HEAT CONTROL

Most everyone of our readers at some time or other has had difficulty in using glue because of the great variance in the flexibility of glue mainly due to uneven heating. Glue, like most other similar substances, has a certain point of temperature where it attains its greatest flexibility and viscosity.

U. S. Government Experimental Stations have established and scientifically proven that glue is most readily applicable and possesses the greatest holding quality at a temperature of 140 deg. to 150 deg.

When glue is permitted to heat to a temperature of 176 deg. or more, it loses its tensile strength. Similarly if it is cooled to 104 deg. or less, there'll be a decided fluctuation in the strength and holding quality.

Thermostatic heat control was recommended but heretofore no one had produced a satisfactory, controlled heat, glue pot which has been fully automatic and required no personal attention.

It is claimed that the Wallace Glue Pot, equipped with a reliable, fully automatic heat control device, is filling the need in an efficient and reliable manner.

There are several exceedingly practical and interesting features incorporated in this new bench glue pot, the foremost of which is of course the automatic heat control which keeps the temperature of the glue between 140 deg. and 150 deg. at all times.—"Steam."

Exports of pulp and paper during October amounted in value to $9,897,356, of which $5,811,954 was in newsprint and $3,936,367 in wood pulp, $49,035 being in other kinds of paper. There were 1,631,043 cwts. of newsprint, and 1,147,199 cwts. of wood pulp shipped. The United States took all but 146,862,000 cwts. of the newsprint exported. As compared with September there was a falling off in the exports of wood pulp, but an increase in those of newsprint.

Clifton Mining Company, at Porcupine, Ont., have installed a steam plant as an auxiliary to electric power.

The construction of a new addition to the plant of the Howard Smith Paper Mills at Cornwall, for the manufacture of bleached soda pulp, will likely be started shortly, according to an announcement made at a directors' meeting held last week. Canadian requirements for this product have so far been imported. The new plant when completed will have a capacity of 15,000 tons per year. The soda pulp will be used for mixing with sulphite pulp to go into the manufacture of certain grades of paper.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we willtell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

DO YOU Manufacture Industrial Equipment?

Are you a manufacturer of twist drills, hack saws, mechanics' tools, wire guards, bolts, rivets, paints—do you manufacture lines of any description that can be used in machine shops, metal-working plants, power plants or foundries? If you do the publications you see illustrated here (Canadian Machinery, Canadian Foundryman, and Power House) can build a bigger demand for your products.

This group of technical newspapers is read by the men who are prospective buyers of your lines. You can bring to the attention of these men the reason why they should demand your goods when purchasing from their dealers. You can effectively do this by placing a message in the paper which serves the field in which your products are sold.

CANADIAN MACHINERY AND MANUFACTURING NEWS is published weekly and covers the machinery, iron and steel and general metal-working industries of Canada.

POWER HOUSE is published twice a month; it serves steam, electrical, water and gas power plants, and the power houses of all general manufacturing plants.

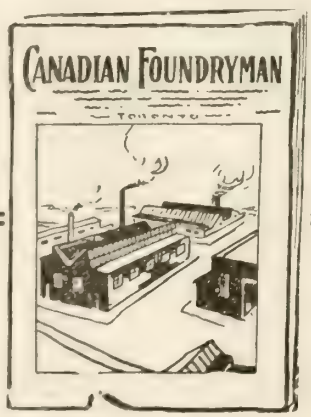
CANADIAN FOUNDRYMAN AND METAL INDUSTRY NEWS is published monthly; it serves the grey iron, steel and non-ferrous foundries.

These publications reach proprietors, managers, purchasing agents, foremen—the men who direct the purchasing of goods. A message to these men in any of the MacLean Technical Newspapers is certain to have a strong influence.

Write for complete Data.

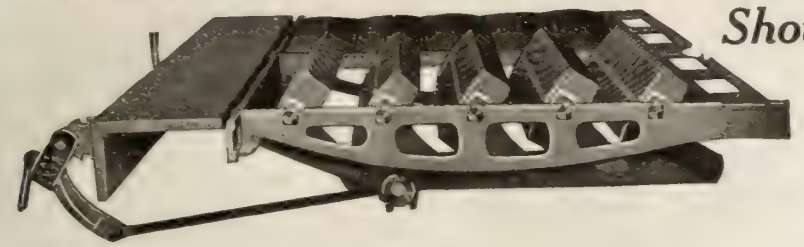
MACLEAN TECHNICAL NEWSPAPERS

153 University Avenue, TORONTO
Montreal, Winnipeg



A Reasonable Saving of 5 to 10%

Should You Expect More?



WE GUARANTEE that with the use of CYCLONE SHAKING AND DUMPING GRATE any grade of hard or soft coal, or screenings of same, can be burned with excellent results both as regards Economy and Capacity; that the total annual expense to the user for coal, interest, depreciation, repairs, damage to boiler, liability of shut-down, etc., will be much less than would be the case with any other type of Grate or Stoker on the market.

The Canadian Steam Boiler Equipment Co.,Ltd.

Sole Makers for Canada

The "ALBANY" Water Sealed ROTARY PUMP

No Valves in These Pumps
Nothing to Get Out of Order

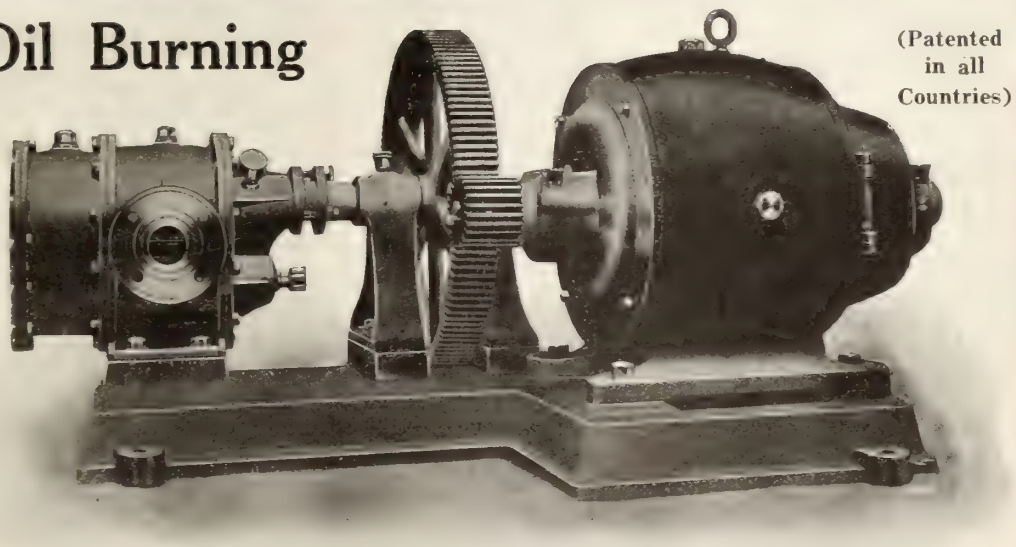
For Fuel-Oil Burning

(Patented in all Countries)

While the "Albany" Patent Rotary Pump is suitable for dealing with gas exhausters, oil, wine, vinegar, brine, acids, spirits, domestic water supplies, etc., it is ideal for fuel-oil burning systems. Made in sizes from 100 to 60,000 gallons per hour.

The "Albany" Water-Sealed Rotary Pump has been approved and used by the British Admiralty for many years. It is favored because of its simplicity, economy and dependability.

Submit your pump problems to us.



Write to-day

Made-in-Canada

As a Vacuum Pump of its type, it has no equal.

Emergencies Prove Its Superiority

It may not be often that the oil film fails in any of your bearings, but the possibility is always present. It is emergencies such as this that test the value of your bearing metals. Magnolia Anti-Friction Metal protects your shafts and bearings from damage in such temporary contingencies. With the lowest frictional coefficient of any known bearing metal—proven by U.S. and foreign government tests—it runs cool with less lubricant and is a safeguard against hot boxes and melting out where lubrication is neglected or may fail for any reason.

Try out a sample Magnolia-lined bearing and test its many advantages for yourself.

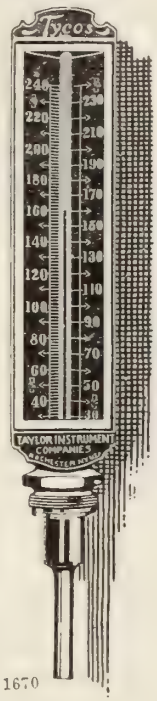
TRADE MARK

Tycos and the Boiler House



Tycos Temperature Instruments give accurate readings under the most strenuous conditions found in boiler rooms. They embody two essentials, namely, accuracy and ruggedness. Because of these factors *Tycos* Temperature Instruments effect considerable coal economy.

Plant operators find solution to their temperature problems in our catalog of boiler room temperature instruments. Please mention firm connection when writing. If the facts are furnished we will help you solve your temperature problems.

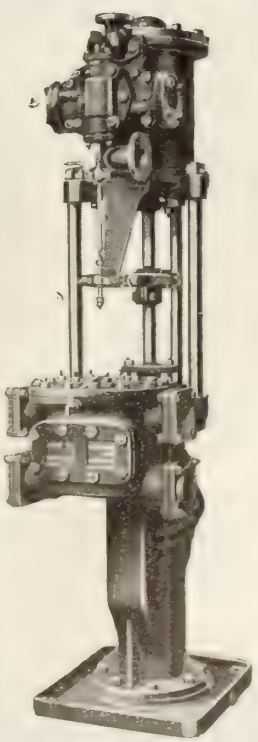
Power House Solves the Problem

It is a dominating factor in maintaining power plant efficiency in equipment and service.

Every issue teems with advertising and editorial matter of a character that will keep YOU right up to the minute in power plant knowledge.

Two Issues per Month
Twenty-four per Year

$2.00 PER YEAR — Every Power Plant employee should read Power House



Canadian Made PUMPS

HEPBURN centrifugal and reciprocating pumps are setting throughout the country a new standard of pump performance and reliability.

Their sterling quality and reasonable price make them the first choice of the discriminating buyer.

JOHN T. HEPBURN, LIMITED

Engineers and Iron Founders

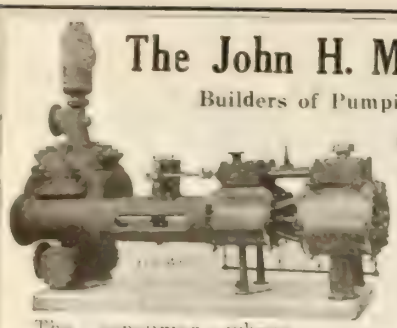
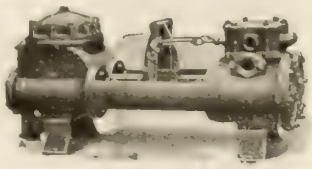
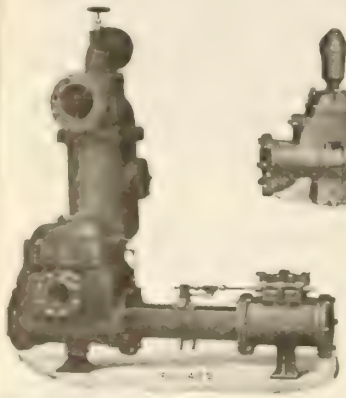
Builders of Pumping Machinery

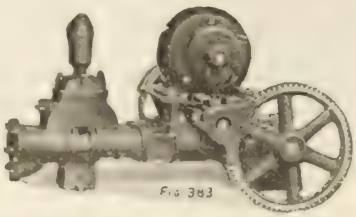
Cincinnati, Ohio, U.S.A



The consumer whose service is interrupted "Can hear no excuse." Reduce complaints by using McGowan Duplex Steam or Power Pumps to handle your water service.







Simple Duplex Steam Power

For All Conditions of Service.

Your boiler room's

temperature cannot affect Copes Regulation

Is your boiler room hot—or cold—or drafty and changeable? It makes no difference in the accuracy of your Copes Feed Water Regulation.

This is proved by more than 400 Copes Regulators operating successfully out-of-doors—in climates that range from 40° below zero to 110° F. in the shade.

A Reliable Application of the "variable water level" principle

The COPES changes the feeding rate according to every change in load; the mechanism which does it is simple, rugged, practically "trouble-proof."

A heavy expansion tube and an almost frictionless valve are its only parts. No springs or diaphragms, no floats or displacement bodies. So simple, and so reliable, that 98 per cent. of the large central stations use the COPES.

Our new booklet "Regulating Boiler Feed Water" gives accurate data on what has been accomplished in other plants, by means of correct boiler feed regulation. Write for Catalog D.

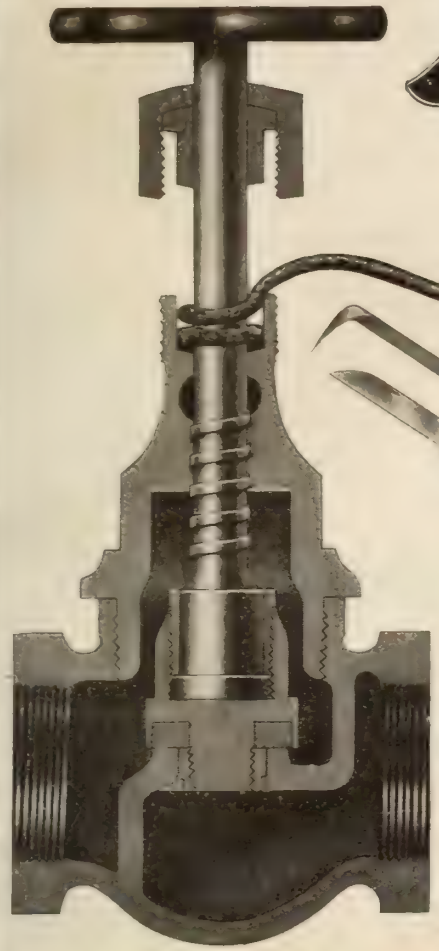
Raybestos PACKINGS

"They Wear Longest"



Reduce Your PACKING Investment

IT MATTERS not whether it be a valve plunger, cylinder head, piston rod or any other operation—you will secure the utmost in service and reduce your packing cost by consistently using **Raybestos.**

Raybestos Packing is Heat-Proof and Acid-Resisting—and it will not harden. It reduces costs.

Raybestos is made from Asbestos secured from Canadian Thetford Mines—its quality is assured.

There is a Raybestos Packing to meet every requirement of your plant. Specify Raybestos Packings. "They Wear Longest."
